## *Abstract*

We identify the returns to schooling in urban China by exploiting individual-level variation in educational attainment caused by exogenous city-wide disruptions to education during the Cultural Revolution from 1966 to 1976. In city-cohorts where disruptions were greater, children's educational attainment became less correlated with that of their fathers and more influenced by whether fathers held administrative positions. Analyzing data from the China Urban Labor Survey (CULS) conducted in 5 large cities in 2001, we estimate the returns to college to be 35 percent using instrumental variables, which is significantly lower than the OLS estimate of 42 percent. In contrast, our IV estimates of the returns to high school average 28 percent, higher than the OLS estimate of 21 percent. The IV and OLS estimates of the mean return to a year of schooling are 7.6 and 8.3 percent. These results are consistent with the selection of high-ability students into higher education through China's college entrance exam system. They are robust to possible biases caused by migration or alternative pathways through which the Cultural Revolution could have affected adult productivity.

Keywords: returns to schooling, wages, education, China

# The Great Proletarian Cultural Revolution, Disruptions to Education, And Returns to Schooling in Urban China

## 1. Introduction

One consequence of the ideological furor of China's Great Proletarian Cultural Revolution, initiated by Chairman Mao Zedong in 1966 and lasting until after his death in 1976, was the widespread disruption of formal education in urban areas. The extent of these disruptions differed across cohorts, across time, and across cities, depending on how zealously new policies were interpreted and implemented locally.<sup>1</sup> As a result, for no other reason than the unlucky location and timing of their birth, the schooling of many Chinese citizens was delayed or cut short, with long-term consequences for occupational attainment and earnings.

In this paper, we estimate the economic returns to schooling in urban China by relying on an identification strategy that exploits a particular feature of how exogenous supply shocks to education caused by the Cultural Revolution affected individual educational attainment. Analyzing data from a survey of workers conducted in five large Chinese cities in 2001, we first show that the Cultural Revolution was a great equalizer of educational access. Prior to and after the Cultural Revolution, children's educational attainment in urban China was highly correlated with the educational attainment of their parents--a nearly universal finding throughout the world. However, during the Cultural Revolution years, among city-cohorts hit hardest by the shocks children's educational attainment became much *less* correlated with that of their parents (see also Deng and Treiman, 1997) and *more* correlated with whether parents held administrative positions.

---

<sup>1</sup>See Pepper (1996) for case studies that describe differences across localities.

We use changes in the correlation between parental characteristics and educational attainment as instrumental variables to estimate the returns to schooling in urban China. An attractive feature of this approach is that the combination of exogenous city-cohort specific disruptions to education and variation in parental education produces individual-level variation in schooling shocks, which enables us to control explicitly for unobserved characteristics of each birth cohort in each city through the inclusion of city-cohort fixed effects. We thus avoid a key weakness of studies that identify the variation in years of schooling solely by cohort differences, such as Ichino and Winter-Ebmer's (2004) study of World War II educational disruptions affecting the 1930-35 birth cohorts in Austria and Germany and Meng and Gregory's (2002a) study of cohorts whose education were affected by the Cultural Revolution. In these papers, the authors are unable to control for unobserved cohort differences that are correlated with both schooling shocks and later productivity, such as those associated with differences in school quality, demographic or policy changes, or major political, social, or economic events that may affect the productivity of entire cohorts.

This paper contributes to a literature summarized by Card (2001) in which measurement of the causal effect of education on labor earnings is facilitated using supply-side factors as exogenous determinants of schooling outcomes. Instruments used in previous studies of the returns to education include quarter of birth (Angrist and Krueger, 1991; Staiger and Stock, 1997), geographic proximity to schools (Kane and Rouse, 1993; Card, 1995), changes in school systems or school leaving age (Harmon and Walker, 1995), special education subsidies for veterans (Lemieux and Card, 1998), and a national school expansion program (Duflo, 2002). Along with Duflo (2002), this is one of the few studies that attempts to identify the causal effect of education in a rapidly growing developing country. In contrast

to her paper which focuses on expansion of primary schools, our paper focuses on shocks that primarily influenced high school and college attainment. Using instrumental variables to identify the true returns to higher levels of educational attainment in developing countries is of particular interest because ability bias in such settings is likely to be substantial given the highly selective procedures often used to allocate scarce entrance slots in institutions of higher education to large pools of potential students. Developing country governments facing severe resource constraints must make difficult choices between investing in higher education or primary and secondary education. Information on the true returns to different levels of schooling can better inform such choices.

Studies that have estimated the returns to schooling in urban China using Mincer-type specifications generally have found that the returns to schooling remained very low by international standards well into the reform period, which began in 1978, but that starting in the mid-1990s there was a steady and dramatic increase in the returns to schooling, reaching very high levels even in comparison to other countries. The best set of consistent estimates over time uses repeated cross-sectional urban survey data from 6 provinces in different regions from 1988 to 2001 and finds that over this period the returns to a year of schooling in urban China grew from 4 percent to over 10 percent (Zhang et al., 2005). In 2001, the return to high school education compared to middle school was 21 percent, and the return to college education compared to high school was 37 percent (Zhang et al., 2005).

These simple estimates of the returns to schooling in urban China are subject to several sources of potential bias, including measurement error in self-reported educational attainment and unobserved ability or school quality. A recent paper by Li et al. (2005) attempts to deal with these problems by comparing earnings differences between identical twins with different levels of educational attainment to reduce bias caused by unobserved

ability. They also use sibling reports of each other's educational attainment as an instrumental variable to deal with measurement error. Analyzing data from five Chinese cities in 2002, the estimated returns to a year of schooling are only 3.8 percent, compared to an OLS estimate of 8.4 percent. As has been pointed out by others, schooling differences between twins are unlikely to be random, so that twins-based estimates will still be subject to endogeneity bias (Bound and Solon, 1999; Neumark, 1999). Nonetheless, the results suggest a much greater degree of ability bias in China than has been found in twins studies in the U.S.

Previewing our main findings, taking the means of our preferred IV estimates, we find that the returns to a year of schooling in urban China in 2001 are 7.6 percent compared to 8.3 percent using OLS, the returns to college education versus high school are 34.7 percent compared to 42.0 percent using OLS, and that the returns to high school versus middle school are 27.3 percent compared to 20.9 percent using OLS. Thus, consistent with ability bias, IV estimates of the overall returns and the returns to college are lower than the OLS estimates. The fact that the IV estimate for the returns to high school is higher than the OLS estimate is also consistent with an ability bias story in which selection into college creates a negative ability bias for those who complete only high school. The results are found to be robust to possible biases caused by sample selection associated with migration or by alternative pathways through which the Cultural Revolution could have affected adult productivity.

The rest of the paper is organized as follows. In section 2, we describe the data and key variables used in the estimation. In section 3, we provide evidence on the disruptive effects of the Cultural Revolution on educational attainment. Section 4 presents the estimating equations for the determinants of log wages and discusses our identification

strategy. In section 5, we present and discuss our estimation results, and section 6 concludes.

## 2. Data and measurement

The China Urban Labor Survey (CULS) was conducted at year-end 2001 by the Institute for Population and Labor Economics at the Chinese Academy of Social Sciences (CASS-IPS), working with provincial and municipal government offices of the National Statistical Bureau. The authors collaborated in the design, training and execution of the survey. The CULS was conducted in five cities: Fuzhou, Shanghai, Shenyang, Wuhan, and Xian. The cities were chosen to be broadly representative of China's different regions. Fuzhou and Shanghai are coastal cities, Shenyang is in the northeast, Wuhan is in central China, and Xian is in western China. Three of the cities are among China's six largest cities by population, and another ranks tenth. In each of the five cities, a representative sample of 700 households whose members were urban permanent residents (holding urban resident permits of the surveyed city) were surveyed.<sup>2</sup> Each household head was asked questions about the household, and then all household members above age 16 and no longer in school were interviewed individually. This resulted in 8109 individual observations. Of these 8109 individuals, 5787 were younger than mandatory retirement age, and 4076 were employed or reported labor earnings at the time of the survey. We exclude self-employed workers because their reported earnings reflect returns to capital as well as labor. We also exclude individuals born after 1978, because many could have still been in school by the time of the

---

<sup>2</sup>Within each city, a three-stage proportional population sampling approach was used to sample an average of 15 registered urban households in each of 70 neighborhood clusters (for details, see Giles, Park, and Cai, 2006) or a discussion of survey protocol on Giles' website (<http://www.msu.edu/~gilesj/Protocol.pdf>). The survey had a non-response rate of 16.5 percent, of which 6.5 percent of households could not be found, 4.9 percent had moved, and 5.1 percent refused to be interviewed. This refusal rate compares favorably with the first round refusal rates of two influential surveys from transition and developing countries: the Russian Longitudinal Monitoring Survey (RLMS) and the Indonesia Family Life Survey (IFLS).

survey in 2001. This leaves us with 3614 observations of urban resident adults between the ages of 21 and 60 who were employed in November 2001.

By focusing on urban permanent residents, the survey excludes those with temporary residence permits or with no registration status, a group consisting primarily of rural migrants. China maintains a household registration (*hukou*) system which discriminates against non-local residents in access to many public services and benefits as well as employment opportunities. Migrants tend to be much younger than urban residents, are likely to have attended schools of poorer quality in rural areas, are more likely to be self-employed, and are a self-selected group who earn lower wages than urban residents even after controlling for observable characteristics (Meng and Zhang, 2002), either due to discrimination or other unobserved differences (e.g., school quality, ability, etc.). For all of these reasons, we focus on the returns to schooling of urban permanent residents only even though the CULS did include a separate survey of migrants in each city. According to the 2000 population census, registered urban households comprised 76 percent of those living in the five sample cities.

The CULS survey instrument asks detailed questions about workers' educational histories. It records the year in which each level of schooling began (primary, lower secondary, upper secondary, vocational high school, college, vocational college, three-year college, graduate school) and the years of schooling completed at each level, including information on repeated grades. From this detailed information, we calculate multiple education disruption variables discussed in section 3 below.

The questionnaire also included questions about the schools attended at each level, which reflect both school quality and early assessments of individual ability that would be otherwise unobserved. These questions include location (city, county, town, village); the

school's province; and whether the student was in a magnet school, an accelerated class in a regular public school, a regular public school class, or a private school. Detailed questions also were asked about the parents of the respondent, including educational attainment, primary industry of employment, occupation, and technical and administrative status.

### **3. Education Disruptions and the Great Proletarian Cultural Revolution.**

In 1966, Mao Zedong initiated a radical political campaign that incited millions of Chinese citizens to revolutionary struggle against corrupt cadres deemed to have betrayed China's Communist revolution. During this tumultuous period, the system of formal education in China's cities was thrown into chaos, while rural schooling was less affected (Meng and Gregory, 2002b). Elementary and secondary education was disrupted for at least six years, and for much of the period from 1966 to 1968 schools in many urban areas were closed altogether. Most universities were closed for six years. Upon re-opening, family political class background status was used as an important determinant of eligibility for admission. Educational disruptions were worse for children with parents who had a bad political class background, and even those with a "middle" background could have been constrained by quotas favoring children of "poor farmers", "workers" and those with "revolutionary" backgrounds, especially at higher levels of education (Pepper, 1996). Universities did not return to merit-based enrollment of students until 1977.

The shock to post-secondary education is evident in Figure 1, which plots administrative data on enrollments in institutions of higher education by year. The figure shows that there were no new entrants to universities from 1967 through 1970, and a sharp drop in total enrollments during the Cultural Revolution. These disruptions are not nearly as evident when we plot the share of individuals with higher education degrees by cohort using

data from the 2000 census (Figure 2). This may be due to the preponderance of correspondence schools and part-time degree programs in the 1980s and 1990s, which enabled individuals to obtain higher education degrees later in life. Also, entering classes contain students from multiple birth cohorts, so that cohort differences in educational attainment will be less obvious than time differences in enrollment. In contrast, the census data plotted in Figure 2 does show clearly the shock to high school completion for Cultural Revolution cohorts.<sup>3</sup>

Reinforcing disruptions created by closure of high schools and universities early in the Cultural Revolution was the “sent-down youth” program (also known as the “rusticated youth” program), under which youth from urban areas were sent to the countryside to live in rural communities. The stated ideological motivation for the program was to help young people get in touch with the revolutionary origins of the Party and to contribute to the country’s rural development. However, the program also has been viewed as a pragmatic response to social unrest in urban areas created by a vast youth population that was neither employed nor in school and stirred to revolutionary furor at the start of the Cultural Revolution (Meisner, 1986). Starting in 1968 large numbers of urban youth of high school and early college ages were dispatched to rural areas, guided by education officials and local revolutionary committees established during the Cultural Revolution. Families were typically allowed to choose one child to keep in the city, but all other children of appropriate age were sent to the countryside. As the Cultural Revolution progressed, students were sent to the country at progressively later ages and some students with favorable class backgrounds were allowed to defer service in the countryside. While rusticated youth were initially expected to

---

<sup>3</sup>Figure A.1 uses the CULS to show college attainment by age 25 with correspondence degrees included and excluded. It is evident that the percentage shock to college education is greater when correspondence degrees are excluded.

spend two years in the countryside, many spent much longer periods of time there because of the lack of available urban jobs. Return from the countryside could be facilitated by college admission, which required a favorable class background through 1977, by joining the military, or by using the connections of a parent, relative, or acquaintance with high enough administrative status to arrange reassignment to an urban job. Most but not all sent down youth were able to return to urban areas after the onset of economic reforms in 1978.

In Table 1, we present descriptive statistics for the sample used in our analyses. We divide individuals into three cohort groups—those whose education was likely to be completed before the Cultural Revolution began (pre-Cultural Revolution cohorts), those whose education was potentially affected by the Cultural Revolution (Cultural Revolution cohorts, born from 1948 to 1963), and those who did not reach school age until after the Cultural Revolution ended (post-Cultural Revolution cohorts).<sup>4</sup> As seen in Table 1, the average years of education and share of individuals completing high school and college were all lower for Cultural Revolution cohorts than for pre- or post-Cultural Revolution cohorts. Moreover, the decline in average educational attainment during the Cultural Revolution occurred even as the average educational attainment of fathers and mothers increased in comparison to the pre-Cultural Revolution cohorts.

We construct three measures of educational disruptions caused by the Cultural Revolution which are specific to each city-birth cohort. First, separately for each city, we measure cohort shocks to high school and college education by calculating the deviation of the actual share of each Cultural Revolution cohort that completed each level of schooling from the cohort trend in these shares calculated from the educational attainment levels of pre- and post-Cultural Revolution cohorts. We calculate shocks to the completion of high

---

<sup>4</sup> These cutoff years correspond to those whose high school education was likely to have been affected by the Cultural Revolution (see below).

school conditional on graduating from middle school, and to the completion of three or four year post-secondary degrees by age 25. We restrict the age of college completion to avoid the influence of degrees acquired later in life on our measure of disruptions during the Cultural Revolution period.

For high school, most cohorts born prior to 1948 would have reached the age of high school graduation in urban areas by the start of the Cultural Revolution in 1966, and cohorts born after 1963 would not plausibly have had high school enrollment affected because the sent-down youth program had ended by their 15<sup>th</sup> birthday. For each individual, the shock to high school faced by individual  $i$  in city  $j$  and birth cohort  $t$ ,  $hshock_{ijt}$ , is calculated as:

$$hshock_{ijt} = htrend_{jt} - hmean_{ijt} \quad (1)$$

where  $htrend_{jt}$  is the trend share of middle school graduates from birth cohort  $t$  in city  $j$  completing high school and  $hmean_{ijt}$  is the actual share of middle school graduates who completed high school.<sup>5</sup> When calculating the value of  $hmean_{ijt}$  for each individual  $i$ , we exclude  $i$ 's own report out of concern that mis-measurement of  $i$ 's shock could be correlated with unobservables. In addition, out of concern that city-cohort sizes may be small for some years and introduce noise or spurious correlations,  $hmean_{ijt}$  is calculated using individuals who completed middle school from the  $t-1$ ,  $t$  and  $t+1$  birth cohorts.<sup>6</sup> We calculate shocks to post-secondary completion ( $ps shock_{ijt}$ ) in a similar fashion, except that the birth cohorts

---

<sup>5</sup>Specifically, the trend line is calculated as:

$$htrend_{jt} = hmean_{j47} + [(hmean_{j64} + hmean_{j65} + hmean_{j66}) / 3 - (hmean_{j45} + hmean_{j46} + hmean_{j47}) / 3] / 17 \times (byear - 47)$$

where  $hmean_{jt}$  is the share of the birth cohort born in year  $t$  and city  $j$  who completed high school.

<sup>6</sup>We find that the results of our analysis are robust to using education shocks for year  $t$  cohorts as an alternative to the three cohort average.

potentially affected by the Cultural Revolution are from 1945 to 1963 instead of 1948 to 1963 as for high school.<sup>7</sup>

Our third education disruption variable measures the scope of the sent down youth program for each cohort in each city. For individual  $i$  in city  $j$  from birth cohort  $t$ ,  $sdsbock_{e,ijt}$  is calculated as the share of individuals other than  $i$  participating the program over the  $t-1$ ,  $t$ , and  $t+1$  birth cohorts.

We plot average values of these three disruption variables for different birth cohorts in Figure 3. Positive values reflect greater disruption (lower educational attainment relative to trend or greater share of individuals affected by the sent down youth program). The negative disruption for high school completion for cohorts born after 1956 reflects the expansion of high school education that occurred during the latter half of the Cultural Revolution.<sup>8</sup> Perhaps most striking is the significance of the sent down youth program. For each cohort born from 1948 through 1958, 30 percent or more were sent to the countryside. The peak cohort was for 1951, of which 50 percent were sent down youth.

As noted earlier, our identification strategy focuses on how educational disruptions altered the relationship between parental characteristics and educational attainment to create individual, within-city-cohort variation in the effects of the Cultural Revolution on educational attainment. Relative to pre-Cultural Revolution cohorts, we expect that parental education mattered less in determining children's educational attainment during the Cultural Revolution years. The children of elites (those with bad class backgrounds) likely had a harder time gaining access to education than the children of non-elites, but our identification

---

<sup>7</sup>Regular college enrollment was affected for a longer period because competitive examinations were not reinstated for college admission until 1977 for the class entering in 1978, and those individuals leaving school after 1966 were allowed to sit for college entrance examinations through 1981.

<sup>8</sup>Pepper (1996) notes that after 1972 there were efforts to expand high school graduation rates which were later scaled back.

approach works as long as education privileged the children of educated children less during the Cultural Revolution period than in other periods. This would have happened, for instance, if the Cultural Revolution made educational attainment more universally accessible, even if it did not discriminate against children of elites.

We also hypothesize that parental administrative status became more important for educational attainment during the Cultural Revolution. This would be the case if during the Cultural Revolution parents in high administrative positions could influence whether and where their children were sent to the countryside, reduce their time spent in the countryside as rural sent-down youth, or increase their chances of getting into college. For example, students sent to better rural locations or who returned earlier to urban areas would have a better environment for self-study that would increase their chance to pass the college entrance exam. In some cases, connected parents might even have been able to directly influence college admissions decisions during the period 1972 to 1977 when such decisions were based on political, rather than academic, considerations. We define father to be a high administrator when his highest achieved administrative status was at the level of division manager (*chu*), bureau director (*ju*) or above.

To illustrate the changes in the intergenerational correlation of educational attainment associated with the Cultural Revolution, in Figure 4, for each city we plot partial correlation coefficients for fathers' and children's years of schooling by birth cohort.<sup>9</sup> In each city, the correlation falls during the Cultural Revolution years and recovers thereafter, with the exact timing and magnitude of these changes varying across cities. The Cultural Revolution thus appears to have succeeded in temporarily weakening the strong correlation between the educational attainment of fathers and their children that is found in most

---

<sup>9</sup> The partial correlations control for differences in fathers' administrative status

societies. This finding echoes that of Deng and Treiman (1997), who analyze census data to examine trends in the intergenerational correlation in educational attainment for households in which parents co-reside with their adult children.

To examine these relationships more rigorously, we estimate a binary response probit model,  $G(\cdot)$ , where the determinants of the probability of individual  $i$  from city  $j$  and cohort  $t$  to complete a certain level of education,  $ED_{ijt}$ , is modeled as follows:

$$P(ED_{ijt} = 1) = G(\gamma_1(fed_{ijt} \cdot eshock_{jt}) + \gamma_2(fad_{ijt} \cdot eshock_{jt}) + \mathbf{X}_{ijt}\boldsymbol{\beta} + \mathbf{cohort}_{jt}) \quad (2)$$

Here  $eshock_{jt}$  is a cohort specific shock to education (alternatively  $hshock_{jt}$ ,  $pshock_{jt}$  or  $sds shock_{jt}$ ) that is interacted with father's years of education,  $fed_{ijt}$ , and interacted with whether father held high administrative status,  $fad_{ijt}$ . Direct values of  $fed_{ijt}$  and  $fad_{ijt}$  are included among a vector of individual, family, and school characteristics,  $\mathbf{X}_{ijt}$ . Also included are age and age-squared measured to the month as well as the school and ability variables described earlier. Finally, we include a vector of city\*cohort dummy variables,  $\mathbf{cohort}_{jt}$ , to control for fixed cohort effects in city  $j$  and time  $t$ . These dummies as well as other variables in the regression are defined for three-year city-cohorts.<sup>10</sup> Given this rich set of control variables, the coefficients on the interaction terms,  $\gamma_1$  and  $\gamma_2$ , identify how education shocks affect how educational attainment is influenced by differences in fathers' education and administrative status.

---

<sup>10</sup>Specifically, cohorts are in the following three-year groupings at the city: 40-42, 43-45, 46-48, 49-51, 52-54, 55-57, 58-60, 61-63, 64-66, 67-69, 70-72, 73-75, and 76-78. Using one-year cohorts leads to a model that is exactly determined for some city-birth year cohorts. Nonetheless, estimated marginal effects do not differ qualitatively whether we use one-year or three-year cohorts.

In Table 2, we present estimation results for the determinants of college and high school completion using equation (2) and different combinations of education shock variables. In the first four columns, we examine the effect of cohort shocks to education on the probability of completing college. We first look separately at the effects on college completion of shocks to college completion, shocks to high school completion, and shocks due to the sent down youth program. For each model, the coefficient on the interaction of the education shock variable with father's years of schooling carries a negative sign and the interaction with the dummy for whether the father has a high administrative position carries a positive sign. Moreover, in each of the models at least one of the two coefficients on the interaction terms is statistically significant (see results in columns 1, 2, and 3). The results suggest that a decline in the share of a cohort attending college or high school has a more pronounced negative effect on the probability of attending college for children with well-educated fathers, or alternatively, that fathers' education has less of an effect on children's educational attainment for cohorts subject to greater educational disruptions. We also find that if the father is a high administrator, children are relatively more likely to attend college if the education shock is greater in magnitude. In column (4), we present results for the case in which all three education shock variables are interacted with father's years of schooling and father's administrative status. In all models of college completion, the interaction terms are jointly statistically significant. When all three sets of interactions are included, they are statistically significant at the 99 percent confidence level.

In columns (5) through (7), we present the results for the determinants of high school completion using shocks to high school and shocks caused by the sent down youth program. Children with more educated fathers are relatively less likely to complete high school when the cohort shock to high school is greater, but there is a statistically and

economically insignificant effect of father’s administrative status (column 5). Similarly, a higher share of one’s cohort participating in the sent down youth program is associated with lower probability of completing high school when father’s have higher education (column 6). When both sets of interactions are included (column 7) the coefficients on the interactions are not independently significant, but they remain jointly significant at the 90 percent confidence level.

#### 4. Estimating the Returns to Schooling

Starting with a standard Mincer-type wage regression, we model the log wage of individual  $i$  in birth cohort  $t$  in city  $j$  ( $w_{ijt}$ ) to be a linear function of schooling ( $\mathbf{S}_{ijt}$ ), measured either in years or as levels of attainment (college, high school and middle school). To control for city and cohort effects created by unobserved differences in school quality and local policies, we first include vectors of city and cohort dummies separately, and then interactions of these dummies to allow cohort effects to vary across cities. We use ordinary least squares (OLS) to estimate the following equation:

$$w_{ijt} = \beta_0 + \beta_1 \mathbf{S}_{ijt} + \mathbf{X}_{ijt} \boldsymbol{\beta}_2 + \sum_{j=2}^J \gamma_j + \sum_{t=2}^T \lambda_t + u_{ijt} + \varepsilon_{ijt} \quad (3)$$

where  $\gamma_j$  and  $\lambda_t$  are city and birth cohort effects, and  $\mathbf{X}_{ijt}$  includes age and age-squared (measured to the month). To highlight the likely endogeneity bias, we include an omitted variable,  $u_{ijt}$ , which is correlated with both  $\mathbf{S}_{ijt}$  and  $w_{ijt}$  (e.g., unobserved ability).

After first estimating a simple Mincer equation, we gradually build up to the more complete equation. We first add city-cohort dummies, which can be expressed as follows:

$$w_{ijt} = \beta_0 + \beta_1 \mathbf{S}_{ijt} + \mathbf{X}_{ijt} \boldsymbol{\beta}_2 + \sum_{j=2}^J \sum_{t=2}^T \lambda_{jt} + u_{ijt} + \varepsilon_{ijt} . \quad (4)$$

We next add to the set of control variables  $\mathbf{X}_{ijt}$ , including gender (dummy for female), height (the z-score within gender), gender\*height,<sup>11</sup> and parent and family background variables (father and mother’s years of education, parent occupation dummy variables, number of siblings). Finally, we add the school quality and ability variables. We expect to observe a fall in the estimated coefficient on years of schooling as we introduce more variables that proxy for ability, family support, or school quality.

China’s selective educational system restricts access to higher levels of schooling to high ability students, so that  $u_{ijt}$  is likely to lead to upward bias in the estimated returns to schooling. Identifying the causal relationship between schooling and earnings requires a valid instrument that is correlated with  $\mathbf{S}_{ijt}$  but uncorrelated with  $u_{ijt}$ . To implement the strategy described above, we first generate predicted probabilities for high school and college enrollment from the probit models (results in Table 2) and then use these predicted probabilities as instruments.<sup>12</sup> Note that the models shown in Table 2 include the same rich set of covariates proxying for dimensions of unobserved ability that we include in the second stage of our IV models, and that identification comes entirely from the interactions of cohort-specific education shocks with father’s education and administrative status.

We first present three panels of results for OLS models (Table 3). In column (1) we estimate equation (3), regressing log wage on schooling, age, age-squared, and city and birth cohort dummy variables. In column (2) we estimate equation (4), including interactions of

---

<sup>11</sup>Controlling for height, which is most heavily influenced by early childhood nutrition which predates educational disruptions, may be important because early childhood nutrition strongly predicts later educational attainment (Almond, 2006).

<sup>12</sup>See Wooldridge (2002) pages 139-141 for a general discussion of the use of generated instruments and Chapter 18 for use of predicted probabilities from a probit model as instruments.

three-year birth cohort dummy variables and city dummy variables. This turns out not to have a significant effect on the coefficient on schooling in any of the models estimated. In column (3), we add the additional covariates other than school quality. The estimated return to college falls from 50 to 47 percent, and the return to a year of education falls from 9.6 to 8.9 percent. In column (4) we add school quality and parent occupation and administrative status variables. The return to college education falls from 4.7 to 4.2 percent, while there is little appreciable change in the return to high school over middle school. The return to a year of schooling falls from 8.9 to 8.3 percent (Panel B). Finally, using piecewise linear spline models, we find that the return to a year of post-secondary schooling falls from 12.9 to 11.9 percent, but we do not observe an economically significant change in the return to schooling through high school (Panel C). These results suggest to us that upward ability bias may be more pronounced at higher and more selective levels of education.

We present the results of implementing our IV estimation strategy in Table 4. For reference purposes, OLS results from column (4) of Table 3 are reproduced in the first column of each panel. In Panel A, we use predicted probabilities from models (4) and (7) of Table 2 as instruments for college and high school, respectively. With probabilities from these models predicted by all available interacted cohort shocks affecting college and high school, our estimates in column (2) are exactly identified. Consistent with ability bias, IV estimates of the returns to college are lower than the OLS estimates. The return to college relative to high school falls by 17 percent from 42.0 percent to 34.7 percent. However, the return to high school relative to middle school rises from 20.9 to 28.2 percent. This contrasts with the findings of Li et al. (2005) who find that for twins, the return to high school compared to not completing high school is not statistically different from zero (their estimate of a 37 percent return to college is quite close to ours). The higher IV estimate of

the returns to high school compared to OLS is consistent with an ability bias story in which selection into college creates a negative ability bias for those who complete only high school. In column (3), we present IV estimates using predicted probabilities from pairs of interaction terms in columns (1), (2) and (3) of Table 2 for college, and columns (5) and (6) for high school. Our IV estimates of the returns to college and high school education are virtually unchanged, and the instruments easily pass an over-identification test.

Overall, we observe a decline in the estimated return to a year of schooling from 8.3 percent to a range of 7.5 to 7.7 percent in our IV estimates (Panel B of Table 4). Examining the differences in the return to a year of post-secondary schooling relative to returns to a year of schooling for grades 1 through 12, we obtain results consistent with positive ability bias for college and negative ability bias for high school (Panel C). Comparing the results of OLS to IV, we find that the 12 percent per year return to college education falls to 8.4 percent per year, while the return to a year of high school education rises from 5.3 to 7.0 percent.

## **5. Robustness**

### **5.1. Migration and sample selectivity**

One concern about our sample is that it consists of only individuals who were living in the sample cities at the time of the survey in November 2001. It is possible that a large number of individuals educated in each city currently lived elsewhere, for example due to migration to other cities or because they were sent down youth who never returned to the city. If the extent and nature of sample selectivity varied across cohorts in a manner correlated with magnitude of educational disruptions, this could introduce bias to our estimates. Changing selectivity could lead us not only to mismeasure the extent of

disruptions caused by the Cultural Revolution for different cohorts, but also to misattribute changes in the correlations among variables (such as changing parent-child correlations in educational attainment) to educational shocks instead of changes in selectivity bias. Despite this potential, one would still require a specific story of how cohort specific selectivity bias is correlated with the magnitude of education disruptions to question whether the IV estimates are biased (we were unable to do so).

It is possible to study the magnitude of sample selection by analyzing data from the 2000 census, which asked about respondents' current place of residence, the province in which they were born, and their current residential registration status (agricultural or non-agricultural *hukou*). We can then examine, at the province level, educational attainment outcomes for individuals registered as urban residents and currently living in urban areas, for urban-registered individuals born in the province and continuing to reside in the province, and for urban-registered individuals born in the province and living anywhere in the country. In Figure 5, we present evidence on educational attainment for these three different groups for each CULS province.

The results for Shanghai are particularly instructive because Shanghai is both a city and a province, so that the census results are for the same urban area surveyed by the CULS. Shanghai is also a city that experienced very large educational disruptions. Figure 5 shows that in Shanghai the disruption to education was substantial and virtually indistinguishable for individuals born in Shanghai and still living in Shanghai (the solid black line) and for individuals born in Shanghai and living anywhere in China (the dotted gray line). For the other provinces where CULS cities are located, we also find that the patterns of educational attainment are nearly identical for current urban residents born in the province and still residing in the province (solid black line) and for those born in the province but residing

elsewhere in China (grey dotted lines). Overall, the evidence presented in Figure 5 suggests that selectivity bias associated with migration is very unlikely to be important.<sup>13</sup>

## 5.2. Alternative pathways

Because the Cultural Revolution was a major political event involving many policy changes and significant social turmoil, one might be concerned that educational disruptions are associated with other unobserved impacts of the Cultural Revolution on individuals that are correlated with later productivity. For example, education disruptions could have created mental stress that influenced long-term health outcomes, or could have occurred at the same time as disruptions to the health care system (or be correlated with other policies) which affected health outcomes. The latter effect, however, is unlikely because it requires that correlated policies have age-specific effects similar to educational disruptions (for example, they should affect school-age children but not pre-school age children). For our estimates to be biased due to alternative pathways, it also would require that the magnitude of Cultural Revolution effects on alternative pathways be correlated with parental characteristics in the same way as educational outcomes.

One way to address the concern about alternative pathways is to evaluate the extent to which our instruments are correlated with measures of those alternative pathways, such as physical and psycho-social health outcomes. To do this, we regress dummy variables for chronic illness, physical deformity, and an index of psycho-social health on the same set of regressors and instrument sets used in the first stage regressions reported in Table 2. We

---

<sup>13</sup> Figure 5 also shows that education disruptions due to the Cultural Revolution are not obvious for provinces other than Shanghai. This could be driven by two factors: reporting of correspondence degrees as actual degrees and the fact that disruptions to education were not as great in smaller cities as in large cities. As the power base of the *Gang of Four*, who were viewed as responsible for many of the excesses of the Cultural Revolution, Shanghai was far more strident in promoting revolutionary policies during the Revolution.

present results of F-tests for the different instrument sets in Table 5. In no case are the instruments found to be jointly statistically significant, so there is no evidence that educational disruptions are systematically related to health outcomes. This contrasts sharply with the results presented in Table 4, which show that our instruments for college and high school enrollment have F-statistics well over 20 in every instance.

## **6. Conclusions**

In this paper, we exploit heterogeneous impacts of educational supply shocks associated with China's Great Proletarian Cultural Revolution from 1966 to 1977 to identify the causal effect of schooling on wages. An advantage of our approach is that, unlike prior studies based on cohort comparisons, we examine variation in shocks to individuals within city-cohorts, which enables us to control for the many cohort differences within cities that are likely to be correlated both with productivity and the timing of the Cultural Revolution, e.g., school quality.

We find that IV estimates of the returns to college are significantly lower than OLS, while the opposite is true for the returns to high school. We interpret these results to be evidence of selectivity bias associated with higher ability students entering college. This is an important finding because it suggests that simple estimates of the returns to schooling in countries with highly selective entrance exams that affect school progression are likely to overestimate the returns to higher education, which could lead policy-makers to over-invest in expanding access to higher education relative to lower levels of schooling.

Three Year Birth Cohort x City Dummy Variables	No	Yes	Yes	Yes
Height, Female and Height x Female	No	No	Yes	Yes
Parent Education Variables and Number of Siblings	No	No	Yes	Yes
School Quality and Parent Occupation Variables	No	No	No	Yes
N	3613	3613	3610	3610
R-Squared	0.302	0.316	0.329	0.341

Notes:

All models include measures of age and age-squared (age is measured from month of birth to November 2001), height (in centimeters), an indicator for gender (female=1), and height x gender. Robust standard errors are cluster corrected at the city-birth cohort level.

**Table 4**  
**Returns to Education**  
**IV Models**

<b>Panel A: Returns to Middle School, High School and College Attainment</b>			
Model #	1	2	3
Model	OLS	IV	IV
Dependent Variable	ln(wage)	ln(wage)	ln(wage)
College*	0.420 (0.030)	0.347 (0.162)	0.347 (0.162)
High School*	0.209 (0.029)	0.282 (0.117)	0.273 (0.116)
Middle School	0.234 (0.064)	0.202 (0.090)	0.210 (0.089)
Significance of Instruments			
College: F-Test	-	72.32	35.18
F-Probability	-	0.000	0.000
High School: F-Test	-	131.52	59.19
F-Probability	-	0.000	0.000
Over-Identification Test			
Hansen J-Statistic	-	-	2.85
Chi-Square P-Value	-	-	0.415
Observations	3611	3599	3599
R-Squared	0.324	-	-
<b>Panel B: Returns to Years of Schooling -- Linear in Schooling</b>			
Model #	1	2	3
Model	OLS	IV	IV
Dependent Variable	ln(wage)	ln(wage)	ln(wage)
Years of Schooling	0.083 (0.004)	0.077 (0.018)	0.075 (0.018)
Significance of Instruments			
Years of Schooling: F-Test	-	76.46	40.22
F-Probability	-	0.000	0.000
Over-Identification Test			
Hansen J-Statistic	-	0.19	3.26
Chi-Square P-Value	-	0.664	0.516
Observations	3610	3598	3598
R-Squared	0.333	-	-

**Table 4 Continued on Next Page**

Table 4 Continued

<b>Panel C: Returns to Years of Schooling -- Piecewise Linear Spline</b>			
Model	1	2	3
Variable	ln(wage)	ln(wage)	ln(wage)
Years of Schooling for Years>12	0.119 (0.007)	0.092 (0.040)	0.084 (0.039)
Years of Schooling for Years<=12	0.053 (0.008)	0.068 (0.027)	0.070 (0.026)
Significance of Instruments			
Years of Schooling >12: F-Test	-	53.46	24.85
F-Probability	-	0.000	0.000
Years of Schooling<=12: F-Test	-	159.13	67.20
F-Probability	-	0.000	0.000
Over-Identification Test			
Hansen J-Statistic	-	-	3.21
Chi-Square P-Value	-	-	0.361
Observations	3610	3598	3598
R-Squared	0.341	-	-

Notes To Table 3:

(1) All models include jointly significant three year birth-cohort X city dummies, school quality and location variables, parent occupation dummies and educational attainment variables, number of siblings, age and age-squared (with age measured from month of birth to November 2001), gender (female=1), height, and gender x height, and jointly significant three-year birth cohort x city dummy variables. We report robust standard errors that are cluster corrected at the three-year birth cohort x city level.

(2) Instruments for high school and college in model (2) are predicted probabilities of college completion calculated from model (4) and of high school completion from model (7) in Table 1. Note, this model is exactly identified in Panels A and C, and so we do not report an over-identification test.

(3) Instruments in model (3) are predicted probabilities of high school attainment from models (5) and (6) of Table 1, and predicted probabilities of college attainment using models (1), (2) and (3) from Table 1.

**Table 5**  
**Test of Potential Significance of Alternative Channels for Cultural Revolution Effects**  
**F-Statistics on Instruments from Alternative First-Stage Regressions**

Model		1	2	3
		OLS	OLS	OLS
Instrument Set		Chronic Illness?	Physical Deformity?	Pscho- Social Health
Instrument Set 1: Predicted Shocks to High School and College From Models (6) and (3) of Table 1	F-Test	0.93	0.21	1.45
	F-Probability	0.395	0.808	0.236
R-Squared		0.1211	0.107	0.078
Instrument Set 2: Predicted Shocks to High School and College From Models (1), (2), (3), (7) and (8) of Table 1	F-Test	0.76	0.81	1.14
	F-Probability	0.579	0.542	0.317
R-Squared		0.122	0.107	0.079

Notes:

(1) All models are estimated using 3599 observations.

(2) Each model above is estimated as a reduced form with predicted shocks to high school and college included as regressors. All models include the non-shock control variables included the models of Table 1: number of siblings, dummy variable for missing information on siblings and mother and father's education, vectors of school quality and location variables, parent occupation dummy variables, and (city) x (three-year birth cohort) interactions.

(3) Instrument Set 1: Predicted probabilities from models (4) and (7) of Table 1.

(4) Instrument Set 2: Predicted probabilities from models (1), (2), (3), (5) and (6) of Table 1.
