

Employment Risk and Performance

Susan Godlonton¹

Preliminary Draft Version, 23rd September 2012

Abstract

This paper examines the impact of employment risk on performance. To induce exogenous variation in employment risk, I randomize outside options for job seekers undergoing a real recruitment process. I do this by assigning job seekers a 0, 1, 5, 50, 75 or 100 percent chance of alternative employment of the same duration and wage as the jobs for which they are applying. Reducing employment risk by offering these outside options reduces the incentive to exert effort in the recruitment process while simultaneously reducing the stress experienced during recruitment. While performance is increasing in effort, it is inverse-u shaped in stress resulting in an ambiguous prediction of the impact of employment risk on performance.

I find that performance is highest and effort is lowest among those assigned the lowest employment risk (a guaranteed alternative job), and performance is lowest and effort highest among those facing the highest employment risk (those without any job guarantee). In the absence of a stress response we would expect both effort and performance to increase unambiguously which is inconsistent with my findings. My findings are consistent with a framework in which performance is determined by both effort and stress. The results are not consistent with gift-exchange, stereotype threat or the nutritional efficiency wage hypothesis.

The performance improvements have significant welfare implications. In this study, job seekers assigned high probability of an outside option were twice as likely to be hired in the standard job recruitment process compared to those assigned low probability of receiving an outside option. More broadly, these results suggest that stress-induced performance reductions are a potential mechanism through which exposure to high employment risk can sustain poverty.

This project was supported with research grants from the Rackham Graduate School, and the African Studies Center at the University of Michigan. I gratefully acknowledge use of the services and facilities of the Population Studies Center at the University of Michigan, funded by NICHD Center Grant R24 HD041028. I acknowledge Ernest Mlenga and his recruitment team for their willingness to provide their recruitment data as well as enabling the integration of this research into their recruitment process. I also acknowledge Kelvin Balakasi for his field and research assistance in Malawi and Soo Ji Ha for her research assistance in Michigan. I thank Sarah Burgard, David Lam, Jeff Smith, Rebecca Thornton, Emily Beam, Jessica Goldberg, and Caroline Theoharides for valuable comments as well as seminar participants at the North East Universities Development Consortium 2011, University of Cape Town, Center for Study of African Economies Conference 2012, and Midwest International Economic Development Conference 2012.

1. Introduction

Currently the world faces a “job crisis” with 200 million people worldwide unemployed and looking for work (ILO, 2012). The individual and social consequences of unemployment are well-documented in many disciplines. In economics, some of the effects of unemployment include reductions in future employment probabilities and wages (Stevens, 1997; Chan and Stevens, 2001; Ruhm, 1991a and 1991b; Topel, 1990), reduced access to credit (Sullivan, 2008); higher crime (Raphael and Winter-Ebmar, 2001; Edmark, 2005), and increased marital dissolution (Jensen and Smith, 1990).² Other disciplines such as public health and psychology document associations of unemployment with poorer mental and physical health, stress and suicide.³

In economics, the literature studying the consequences of unemployment has focused either on the effects of a bad employment realization; or on risk mitigation mechanisms.^{4,5} However, the impact of employment risk is not well-studied.⁶ This is true for a number of reasons. First, employment risk is usually endogenous with key economic outcomes of interest. For example, in the case of performance, individuals of higher ability are likely to face lower employment risk yet also perform better on average. Second, while laboratory experiments enable scope for inducing exogenous variation they are limited in providing insights into real world behaviors. Third, measuring performance particularly in contexts outside of laboratory experiments is difficult due to self-report biases and lack of good quality firm level data particularly in developing countries.

In this paper, I overcome these challenges by explicitly varying employment risk using a randomized controlled trial to examine the impact of employment risk on performance. I randomize job-seekers’ outside options during a real recruitment process working in collaboration with a real recruiter offering short-term jobs. I randomly assign 268 job-seekers a probabilistic chance (0, 1, 5, 50, 75 or 100 percent chance) of an alternative job. This reduces the downside risk of performing poorly during the

² The recent World Development Report (2013) provides an extensive review of the key impacts of unemployment.

³ Unemployment has been found to be correlated with physical health (Brenner, 1971 and 1979; Jin, Shah and Svoboda, 1995); alcohol consumption (Brenner, 1975); mental health (Dooley, et al. 1994 and 2000; Murphy and Athanasou, 1999); suicide (Lundin and Hemmingsson, 2009).

⁴ Often this empirical work use an exogenous shock that results in job loss such as plant closures and retrenchments to examine both short term and long term consequences on future employment, and earnings (Stevens, 1997; Chan and Stevens, 2001; Ruhm (1991a, 1991b); Topel, 1990; Schoeni and Dardia, 1996; Gregg, 2001; Gregg and Tominey, 2005; Couch, 2001).

⁵ A second strand of relevant literature examines risk coping mechanisms and their impacts in the labor market. This literature has examined the role of unions (Magruder, 2012), unemployment insurance (Gruber, 1997; Browning and Crossley, 2001; and Green and Riddell, 1993) and informal networks (Burns, et al. 2010, Beaman and Magruder, 2012) and how individuals use these support structures to mitigate risk of unemployment.

⁶ As discussed in-depth in Fafchamps (2010), shocks and risk are often used interchangeably despite being distinct. He highlights the lack of research on the impact of any type of risk in the empirical development literature noting that the literature has instead focused on the effects of shocks ignoring the anticipatory nature of the shocks. This is in contrast to older theoretical work that has explicitly addressed this and shows that risk aversion should lead to underinvestment and underproduction (Sandmo, 1971).

recruitment process. For those receiving a guaranteed outside option employment risk is zero. To examine the impact of employment risk on performance and effort, I utilize both objective and subjective performance assessments from administrative data as well as administrative and self-reported effort measures

Drawing on economic and psychological insights, reducing employment risk likely affects performance through two key channels. First, by improving a job-seekers' outside option, the incentive to exert effort during recruitment is reduced. Therefore, as outside options increase, effort in the recruitment process should decline, and therefore so too should performance. I refer to this as the *incentive effect*. Second, the psychology and public health literature shows that uncertain employment prospects are stressful (Feather, 1990; de Witte 1999, 2005; Burgard et al., 2009). Therefore, by improving a job-seekers' outside option the job-search process should be less stressful. This reduction in stress has performance implications as Yerkes-Dodson (1908) show that performance has an inverse U-shaped correlation with stress. Therefore, as stress decreases due to improved outside options, performance could increase or decrease. I refer to this as the *stress effect*. Research on the implications of stress on performance is under-studied within economics. The research that does exist focuses on how stress affects performance in professional activities, sports performance and academic settings.^{7,8,9}

Depending on the sign of the stress effect and relative magnitudes of the stress and incentive effects, the impact of reduced employment risk on performance could be positive, negative or neutral. Also, within this framework reducing employment risk should unambiguously result in declining effort.

I find evidence suggesting that the stress effect outweighs gains from the incentive effect, resulting in overall increases in performance, despite decreases in effort, when employment risk is lowered. That is, I find that sufficiently improving a job-seekers' outside option leads to improved performance while effort declines. Job-seekers assigned a guaranteed outside option performed 0.3 to 0.45 standard deviations better than those that received no outside option on recruiter administered tests testing knowledge taught in training. I also observe higher average quality engagement in training by

⁷ In the public health and industrial psychology literatures, stress has been shown to be correlated with performance among nurses, medical doctors, policemen and teachers (Jamal, 1984; Motowidlo, 1986; Spurgeon and Harrington, 2007; Sullivan and Bhagat, 1992; Band and Manuele, 1987).

⁸ The literature on sports performance presents relatively mixed results. Primarily this literature has looked at the probability of scoring penalty kicks in professional soccer. Dohmen (2008) finds that when the importance of scoring is greatest, individuals tend to score. Apestequia and Palacios-Huerta (2010) find that players who shoot second in a penalty shoot-out lose 60.5 percent of the time. They argue that this is driven by increased pressure to perform, and identification is achieved because the order of the shoot-out is determined randomly from a coin flip. However, Kocher et al (2011) fail to replicate these findings using a different dataset. Paserman (2010) examines performance in tennis and sets up a structural model. He finds that individuals would be substantially more likely to win if they could score when it mattered most.

⁹ The literature examining high-stakes testing also finds mixed evidence. Ors et al. (forthcoming), find that women perform worse on a high-stakes entrance exam for an elite University relative to men despite higher performance on other low-stakes exams in France. In the education literature more broadly, testing anxiety has been widely observed and studied. Evidence shows that test anxiety can both increase and decrease performance (Sarason and Mandler, 1952; Tryon (1980) provides an extensive review).

those assigned high outside options compared to those assigned no outside option. For effort indicators I find the reverse, that is, I find job-seekers assigned the highest outside options engage in the lowest effort, while those assigned the lowest outside options engage in the highest effort. In terms of punctuality job-seekers' assigned a guaranteed outside option were 9.3 percentage points more likely to ever arrive late during the training conducted during recruitment compared to those assigned no outside option, however the difference is not statistically significant. I do find large, robust and statistically significant differences in self-reported effort. Individuals assigned a guaranteed outside option spend 25 minutes less per day studying training materials compared to job-trainees assigned no outside option. They substitute this time by increasing their consumption of leisure time.

In sum, I find that performance is highest and effort is lowest among those assigned the lowest employment risk, and performance is lowest and effort highest among those facing the highest employment risk. These results may seem counter-intuitive if one does not account for the role of psychological considerations such as stress.¹⁰

Perhaps the most interesting result I find is that performance is higher among those facing the lowest employment risk. While this is the first study to my knowledge that has examined this question in labor markets, my results are consistent with laboratory experiment findings conducted by Ariely et al. (2009).¹¹ They conducted laboratory experiments among 76 participants in rural India and offered either a high, medium, or low incentive for meeting a performance target on six different games testing concentration, creativity or motor skills. These performance incentives are in some sense the inverse of the variation in my experiment: while I decrease risk, high power incentives increase it. They consistently find that performance in the group assigned the high incentive (400 Indian Rs, equivalent to a month's salary) was always lowest. With the exception of one task, performance in the low incentive group (4 Indian Rs per game) and the medium incentive group (40 Rs per game) were not statistically significant. They conduct additional laboratory experiments among 27 undergraduate students at MIT and try to disentangle changes in effort and performance under the different incentive structures. They find suggestive evidence in support of increased effort but declining performance.

My findings, then, are consistent with Ariely's in the sense that performance is negatively correlated with risk and effort is positively correlated with risk. My contributions go beyond affirming this finding, however. I extend the experiment from the risk associated with wage incentives to study employment risk, a distinct though clearly related construct with potentially larger welfare consequences.

¹⁰ Kamenica (2012) reviews empirical findings within economics where incentives have had anomalous effects.

¹¹ Psychologists have extensively studied conditions under which increased pressure to perform has resulted in choking under pressure. Seminal work is presented in Baumeister, 1984 and Baumeister and Showers, 1986. More recently, Beilock (2010) provides a comprehensive review of this literature covering performance in sporting events, academic environments and professional settings.

I also extend the literature from the lab to the field. The variation in risk in laboratory studies is artificial and over windfall income, but in my setting, the variation is over risk in securing real, meaningful employment equivalent to that subjects have chosen to apply for through a competitive and arduous process. To my knowledge, no evidence in real-world settings has illustrated the link between risk, performance, and effort, and as noted by Kamenica (2012), whether the previous findings will extend beyond the laboratory was previously unknown. Additionally, I collect a rich series of baseline and outcome data in order to incorporate an important strand of the psychology literature, which studies the mechanisms through which risk and uncertainty affect behavior. Many previous studies in economics have only identified the reduced-form relationship between uncertainty or risk and performance, though Angelucci et al. (2012) measures cortisol in a laboratory study of how stress affects entrepreneurship. The data I collect allow me to rule out alternative mechanisms, which I discuss in detail later in the paper. I was unable to measure cortisol but do have data about mental health from the SF-36, as well as heart rate (a measure of arousal) from a smaller pilot study. Finally, my study speaks to the growing literature about the effect of high-stakes testing. My results suggest that the same settings that disadvantage some individuals in educational settings are also likely to affect them when seeking jobs.

In my study, the finding that performance is highest among individuals with guaranteed outside options has important policy implications. First, the performance results have important welfare implications. In this study, differences in employment rates by treatment status show that individuals' assigned a 75- or 100- percent chance of an alternative job were twice as likely to be employed by the recruiter compared to those in the other treatment groups. The broader implications of this are that individuals with greater income support through employment guarantees, cash transfer programs, family support or employment income are likely to perform better. This has positive feedback effects. Poor initial unemployment probabilities can induce stress induced performance reductions resulting in poverty persistence across individuals, communities or countries. Lastly, the results presented yield insights into the types of people that are more likely hired with different recruitment strategies. For example, individuals exposed to higher employment risk have a greater chance of employment in process that place greater emphasis on effort than on performance in their hiring process.

There are a number of other behavioral theories that are consistent with the key result that individuals facing a lower incentive to perform (better outside options) exhibit higher performance. Gift exchange is one possibility. However, I find that individuals exert less effort in studying for the tests during recruitment suggesting that gift-exchange hypothesis is not the explanation in this case. Second, I find that job-trainees' perceptions about their own likelihood of being hired by the recruiter do not significantly differ across treatment groups suggesting that stereotype threat is an unlikely mechanism. Third, the nutritional-wage hypothesis is also unlikely to be the key driver as individuals do not differ in

their food expenditures by treatment group during the training. However, I cannot rule out that there is some other psychological consideration that operates in a similar way to the proposed stress response.

There are some limitations to my findings. First, this study was conducted using short term job opportunities; the effects of longer term job security cannot be assessed in this context. Second, the experiment was among a sample of relatively well-educated men in the capital city of Malawi. This paper cannot speak to how other groups might respond. Third, it would have been optimal to have biomarker indicators to measure stress (e.g. cortisol) but due to logistical and budgetary limitations this was not feasible.

The remainder of the paper proceeds as follows. Section 2 outlines the conceptual framework and Section 3 provides some contextual information about labor markets and recruitment in Malawi and presents the experimental design. Section 4 outlines the different data sources used. Section 5 presents the estimation strategy and Section 6 presents and discusses the results. Section 7 concludes.

2. Conceptual Framework

I examine the impact of employment risk on performance during a recruitment process. To do this, I explicitly vary job-seekers' outside options. There are multiple effects of reducing the downside risk of the recruitment process on performance. First, by offering individuals improved outside options the incentive of performing well during the recruitment process is reduced. Second, by improving job-seekers' outside options the recruitment process is likely to be less stressful. I discuss the implications of these two key channels for performance and effort in this section, and then summarize the key predictions.

Incentive effect

Intuitively an improvement in an individuals' outside option reduces the marginal benefit of any particular employment opportunity. Therefore, the optimal level of effort should decline as outside options improve assuming that the cost of effort is not zero. If performance is increasing in effort, this implies that as outside options improve performance will decline.

In the recruitment setting I study, assume that p is the probability of being hired in the current recruitment process, and w is the wage associated with this job. One can think of the probability of being hired as a proxy for performance. Therefore, $1-p$ is the probability of not being successful in the recruitment process. Also, b is the expected value of the individuals' outside option (i.e. their probability of outside employment multiplied by the expected wage of outside employment). Also, assume that effort is costly. Therefore an individual selects effort level e^* to maximize:

$$\text{Max}_e U = p \cdot w + (1 - p)b - c(e)$$

subject to:

$$\begin{aligned} p &= f(e), & f'(e) > 0 \text{ and } f''(e) \leq 0 \\ c(e) &\geq 0, & c'(e) > 0 \text{ and } c''(e) \geq 0 \end{aligned}$$

We typically implicitly assume that performance is increasing in effort as presented above. Therefore, a reduction in effort leads to a reduction in performance (and therefore the probability of being hired). Empirically, however, if performance is also a function of other psychological factors then performance may not necessarily unambiguously decline. I turn to this next.

Stress Effect:

A second key channel through which employment risk may affect performance is through its impact on stress. Extensive literatures in both psychology and public health show that unemployment is stressful, as is perceived job insecurity (Feather, 1990; de Witte 1999, 2005; Brugard et al., 2009). Therefore, reducing the risk of unemployment should reduce stress. The Yerkes-Dodson law (1908) maps the relationship between stress and performance, where performance is inverse u-shaped in stress. As stress increases performance improves up to a bliss point beyond which performance declines as stress continues to increase (Figure 1a).

If this is true, then the probability of being hired (which can be thought of as a proxy for performance) is a function not only of effort but also of stress, i.e. $p = f(e,s)$, and $f'_s > 0$ or $f'_s = 0$ or $f'_s < 0$. Given the existing evidence that job uncertainty is stressful, it is reasonable to assume that stress is a decreasing function of an individuals' outside options, i.e. $s = s(b)$, and $s' < 0$. In other words, as outside options improve, stress should decline.

Therefore, due to the performance-stress relationship the stress effect may be positive, negative or neutral as outside options improve.

Resulting predictions combining incentive and stress effects

In order then to think about the net impact of employment risk on performance one needs to consider both the incentive and stress effects simultaneously. On the one hand there exists an incentive effect when outside options increase so too should effort and performance. However, as outside options improve, stress is reduced and this could result in a performance improvement or decline. This results in ambiguous predictions for the net effect of employment risk on performance depending on the relative size of the incentive and stress effect. Thus, there are three possibilities when employment risk declines:

- *Performance and effort decline:*

If the stress effect leads to a performance decline, then effort and performance should decline.

Alternatively, if the stress effect leads to a performance improvement but this is smaller in magnitude compared to the incentive effect, then effort and performance will both decline.

- *No change to performance, but effort declines:*

If the stress effect leads to a performance improvement and exactly equals the incentive effect, then we will observe no net effect of employment risk on performance.

- *Improved performance, but effort declines:*

If the stress effect leads to a performance improvement that exceeds the magnitude of the incentive effect then we will observe effort declining and performance improving when outside options are improved.

In sum, for performance indicators it is ambiguous whether performance will increase, decrease, or be constant as outside options vary. Second, effort indicators unambiguously decline as outside options improve.

3. Experimental Design

In order to test the impact of employment risk on job trainee performance, I vary individuals' outside options during a recruitment process. In the absence of this intervention the distribution of job-seekers' outside options is correlated with their own ability, prior work experience, and social networks. I offer job-trainees a randomly assigned probability of an alternative job with the same wage and duration as the job for which they have applied. I work in collaboration with a real recruiter and embed the experimental component into an already existing recruitment process. In this section I provide some background to the experimental setting; I outline the details and timeline of the recruitment process; and provide details of the intervention.

3.1 Setting

Developing country urban labor markets are characterized by high unemployment and underemployment; as well as high job instability (WDR, 2013). In many respects these labor markets are similar to low-income labor markets in developed economies. High rates of in-migration to urban areas in developing countries suggest these problems are likely to increase. Malawi, where this study is conducted, is no exception. It is the fourth-fastest urbanizing country in Africa (HDR, 2009). Data from the nationally representative Integrated Household Survey shows that only 39.8 percent of urban Malawian men aged 18- 49, report ever being employed for a wage, salary or commission in the last 12 months. When examining activity in the last 7 days, 29.6 percent report either engaging in household agricultural activities, running or helping to run household small businesses, engaging in ganyu, or being employed for a wage, salary or commission. Information on job turnover or the prevalence of short term contracting is not well measured. However, sectors that are characterized by high turnover, fixed term

contracts and seasonality are the most common among urban residents. For example, 7.9 percent report working in construction; and 46.8 percent in community, social and personnel services (IHS2010/11).¹²

There is widespread poverty in urban areas and this is not only the case among the least educated. Even relatively well-educated individuals face financial struggles driven by poor labor market conditions, limited social security systems, and significant pressures on their income.

The sample in this paper is restricted to men aged 18 and older who had completed secondary schooling due to the recruiter's eligibility restrictions. Approximately 39 percent of urban men aged 18 to 49 have completed secondary schooling in Malawi. However, they too face high rates of unemployment, only 52.5 percent had worked in the past year (IHS, 2010/11).¹³ Due to their relative higher social status, these men also face considerable financial responsibility not only from their immediate family but often from extended family members. On average these men report sending 10 percent of their wage income to other households (IHS2010/11). Given this disproportionate financial responsibility, they are arguably the group most prone to stress related to income uncertainty.

3.2 Recruitment Process and Timeline

The sample of respondents is drawn from a recruitment process hiring interviewers for a health survey.¹⁴ Contract work on survey projects for government or international organizations, research projects, or NGOs is quite common in the capital city. Data collected by Chinkumba et al. (2012) which samples approximately 1200 men aged 18 to 40 in the Malawi capital finds that one in ten individuals had ever worked as an interviewer, and one in four of those who had completed secondary schooling. This data set also provides some descriptive data on hiring practices.¹⁵ A total of 38 percent report competing for a job, 23 percent report having taken a test for a job, 51.5 percent report undergoing an interview and a third report attending training for their most recent job.¹⁶

¹² The community, social and personnel services sector also includes teachers which have been excluded in calculating the fraction working in this sector as teaching although low-paying it is a stable profession in this context.

¹³ Additionally, 1 percent had been engaged in household agricultural activities; 6.2 percent had run or were assisting to run small household businesses; 1.95 percent were engaged in ganyu and 21.7 percent had been employed for a wage, salary or commission.

¹⁴ The recruiter conducts independent consulting within Malawi and has for several years implemented various randomized controlled trials in Malawi for Universities and other international NGOs.

¹⁵ Unfortunately the Integrated Household survey which would provide nationally representative data asks only a single question related to job search. Individuals who had not worked in the past 7 days are asked whether or not they looked for work in the past four weeks. Moreover, firm level data on hiring practices is not available.

¹⁶ These numbers come from authors own tabulations from unpublished data collected by Chinkumba, Godlonton and Thornton (2012).

In my case, jobs offered by the recruiter are relatively high paying, offering approximately three times the average wage for men who have completed secondary school.¹⁷ However, the wages offered by this recruiter are comparable to those offered by other employers hiring for this type of work.¹⁸

The recruitment process timeline is presented in Figure 2. There are three phases of the recruitment process: pre-screening; training and screening; and final selection. The experimental component was conducted during the training and screening phase.

Recruitment Process: Pre-screening

To advertise positions advertisements are placed in multiple public places.¹⁹ The placement was determined and conducted by the recruiter and followed their standard protocol. The public advertisements notified the public about the job, including eligibility requirements and the application procedure. Only men, aged 18 or older, who had completed secondary schooling were eligible to apply. To apply, individuals were required to take a screening assessment test and submit a copy of their resume.²⁰ The written assessment included numeracy and literacy modules, and a brief background module. A total of 554 applicants wrote this written assessment test. Based on the numeracy and literacy scores from that test, the recruiter selected the top 278 applicants to advance to the job training phase of the recruitment process.²¹

Recruitment Process: Training

The 278 job-seekers that advanced to job training attended a pre-training information session. During this session job trainees were provided logistical information related to the training process and provided materials required for training. They were also informed about the opportunity to participate in this research study. A total of 268 applicants of the applicant pool opted to participate (95 percent). This constitutes the main sample. Consenting participants were asked to self-administer a baseline questionnaire after which they were issued their probabilistic job guarantee. Details related to the nature and assignment of the probabilistic job guarantees are discussed in Section 3.3.

All 278 job-trainees were invited to attend three days of full-time training and further screening. They were paid a wage equivalent to one-half of the daily wage of the employment opportunity. During

¹⁷ The mandated monthly minimum wage for urban individuals is only \$24 per month per day (Duverall and Mussa, 2010). However, more relevant wage information regarding comparable wages can be assessed using the Integrated Household Survey (2010/11). The average wage among men, in urban areas, with completed secondary schooling aged 18 to 49 is approximately \$4.75, the median is somewhat lower at \$2.02.

¹⁸ Wages at institutions hiring interviewers regularly (such as Innovations for Poverty Action, National Statistics Office and others) ranged from 2,500MKW to 5,050MKW per day for urban interviewers. Wages offered in this case are on the low end for this type of work at 2,500 MKW.

¹⁹ These include: public libraries, educational institutions, public notice boards, and along streets.

²⁰ Individuals were encouraged to bring a copy of their resume. Most (95 percent) did bring a resume. Those who did not bring a resume were not prevented from writing the pre-screening assessment test.

²¹ The 278 individuals selected were screened based on a clear cut-off using the numeracy and literacy test administered. The distributions of these scores are presented in Figures 3a and 3b. Given this selection criteria, the sample of interest is a non-representative sample of applicants. However, it is representative of the individuals who were selected for training by the recruiter and therefore captures the population of interest relevant for the research question.

training, applicants were monitored for their punctuality, and engagement in the classroom environment in which they were taught the materials relevant to the health survey for which they were being trained. Individuals were also tested based on materials taught. Summary statistics and details related to these administrative data are discussed in Section 4.

Also, for the purposes of this study on each day of training, respondents were asked to self-administer a survey questionnaire. The recruitment team did not know who chose to participate in the research; what alternative job probabilities were assigned; nor if participants completed the daily questionnaires. Moreover the recruiter did not get access to their survey questionnaires. This was carefully explained to the respondents and monitored to ensure confidentiality regarding participation in the research study.

At the end of the final day of training the alternative job draws were conducted and participants learned their alternative job employment realization. The recruiting team was not present at the time of the probabilistic job draws and they were not at any point informed who received an outside job offer.

Recruitment Process: Selection by Recruiter

Two days after completing the training, the successful applicants for the recruiter were contacted.

3.3 Intervention: Probabilistic Outside Employment Options

During the information session prior to the commencement of the job training, job trainees were randomly assigned some *probability of employment* via a job guarantee for an alternative job. There were six different probabilistic guarantees – 0, 1, 5, 50, 75, and 100 percent chance of an alternative job.²² Thus, the intervention experimentally altered individuals' outside options.

The alternative jobs were constructed to mimic as closely as possible the jobs offered by the recruiter. The alternative jobs were for equal duration and pay as the job being offered by the recruiter. They were real jobs, requiring real effort and paying real wages. While the recruiter is hiring for interviewer positions the alternative jobs were other research jobs so in both cases individuals acquired research related experience. In both cases, individuals were working for research projects for the same University albeit on different projects and performing different types of research tasks. The alternative jobs included data entry, translation, transcription and archival research. If individuals were selected by the recruiter and also received an alternative job they were required to take the recruiter's job and not the alternative job.

²² In a pilot version of this experiment there also existed a 25 percent chance of a job guarantee. However, given the results of the pilot, the sample size required to detect reasonable effect sizes was too large given the financial constraints of this project. For the same reasons while a 99 percent chance of a job guarantee was desired to test differences in small changes in risk (specifically 0 to 1 percent and 99 to 100 percent) due to budgetary limitations it was not possible to implement.

Treatment status was single-blind. Job trainees learned their status in the following manner. Each job trainee was given an envelope with their employment ID written on it. Inside the sealed envelope was a contract stating which probabilistic job guarantee they had received. Job trainees assigned a 0-percent chance of an alternative job also received an envelope.²³ Randomization was conducted at an individual level stratified on quintiles of baseline ability and an indicator variable of whether or not they had ever worked for the recruiter.²⁴ Baseline ability was determined using participants' scores from the numeracy and literacy components of the pre-training assessment test. The distribution of the probabilities was pre-assigned to successful job applicants invited to the information session (278 men). A total of ten individuals opted not to participate in the research project or in the recruitment process. These participants made their decision before knowing which treatment group they had been assigned to. In the final sample of the 268 male participants, the distribution of the probabilistic job guarantees is similar to the intended assignment (Table 1, Panel A).

Prior to learning their own treatment assignment, trainees were informed about the distribution of the alternative job probabilities within the group. The distribution of treatment allocated approximately 20 percent to the 0, 1, 5 and 50 percent chance groups and approximately 10 percent of the sample to the 75 and 100-percent chance groups.²⁵ Respondents were informed about the distribution of the probabilities to ensure that all participants had the same beliefs about the distribution. Had respondents not been told the underlying distribution, then individuals would have variable information about the distribution which would be endogenous to the truthfulness and size of their social network among other job trainees.

Job trainees were also informed that their treatment assignment would not be revealed by the research team to the recruiter or anyone else. To ensure individuals were clearly informed about how the probabilities worked and how the draws would be conducted they were discussed in detail and demonstrations were conducted to illustrate the process. For example, if a job applicant received a probabilistic job guarantee of 75 percent then on the final day of training after training was concluded they faced a bag of 100 bottle tops. In the bag there were 75 red bottle tops and 25 green bottle tops, if the individual drew a red bottle top they would receive an alternative job; if they selected a green bottle top they would not. Similarly, for the other treatment groups.

It was consistently emphasized that their probability of an alternative job would have no direct bearing on their probability of being hired by the recruiter. In fact, no one in the recruitment team knew the distribution or the assignment of the probabilities to job trainees.

²³ Individuals could choose to reveal it to anyone they wanted to but they were not required nor encouraged to do so.

²⁴ "Ever worked with the recruiter" is broadly defined. That is, even individuals who had attended a prior job training session held by the recruiter but had never successfully been employed are included in this category.

²⁵ While equal proportions across groups was desirable this was not feasible due to budgetary limitations.

An important concern is whether individuals actually understood the probabilistic nature of the alternative job offers.²⁶ After the treatment was explained, but before individuals learned their own probability, participants' perceptions related to their understanding of these probabilities were elicited through surveys. Participants were asked for each treatment arm, what they expected the realization of alternative jobs to be. For example: "If 60 participants received the 50-percent job guarantee, how many of them are likely to receive an *alternative* job." For low probability events (1 percent and 5 percent), individuals overestimated the chances of success (mode is 1.6 and 5 percent respectively).²⁷ For the higher probability events (50-, and 75- percent treatment groups) job trainees tended to slightly underestimate the chances of success. The mode for the 50-percent treatment group was 50 while the mode for the 75-percent treatment group was 83.²⁸

4. Data

I use two sources of data in this paper. Primarily, I use administrative data collected by the recruiter. I supplement this with survey data I collected for this project using self-administered questionnaires by respondents and privately submitted in a sealed box at the training venue.

4.1 Baseline Data

Pre-screening assessment test (administrative data): From the recruiter I have data from the screening assessment test that was conducted to select the job trainees. Recall this test consists of numeracy; literacy; and background information modules.²⁹ The average numeracy score was 52.5 percent, and the average literacy score was 70.3 percent among the 554 job applicants. For the sample of short-listed candidates, the sample frame for this paper, the average numeracy score was 63 percent, and the literacy score was 80 percent. The ability score that will be referred to throughout the remainder of the paper is a composite measure of the individuals' numeracy and literacy score. The distribution of the numeracy, literacy and composite ability scores are presented in Figures 3a and 3b.

Baseline questionnaire (survey data): To supplement this administrative data I conducted a baseline questionnaire. The survey instrument was administered during the information session to

²⁶ Although the sample is relatively well educated mathematical literacy particularly related to probability is not universal.

²⁷ Given the phrasing of the question for the 1 percent chance treatment group, it was impossible for individuals to select an integer that would map into 1 percent of the distribution getting alternative jobs. The mode is 1 person is selected which maps to the 1.6 percent, but the second most frequent response recorded was 0.

²⁸ These priors are not differential across treatment status.

²⁹ During the pilot a similar standardized test of literacy and numeracy was used but the literacy component was slightly too easy, and this was adjusted for the population in this implementation. A large proportion of the numeracy module used comes from the South African National Income and Dynamics Survey wave 1 survey. Additional questions come from previous recruitment tests used by the recruiter as well as other survey implementers in the country such as the Malawi National Statistics Office. The literacy module comprises questions taken from the South African Cape Area Panel Study Wave 1 survey and is supplemented with additional more difficult literacy questions.

consenting participants before the commencement of training. It includes questions about previous work experience, employment perceptions and attitudes, physical and mental health indicators, time use, and a work and health retrospective calendar history.

4.2 Training and Post-Training Data

I use administrative data collected during the training as well as the hiring decisions made by the recruiter to construct the key outcome variables of interest used in the analysis. I supplement this with daily follow-up survey questionnaires that were also conducted during the training.

Participation in Training: Table 1 Panel B presents the participation rates of the 268 consenting participants. Most of the selected job trainees opted to participate in the training –94 percent attended training every day. There is no large statistically significant difference in training participation across treatment groups.

Punctuality records: Recruitment staff recorded daily attendance including job trainee arrival times. Participants were required to sign-in when they arrived to determine which classroom they had been assigned to that day. When participants signed-in, their time was recorded. I use the sign-in times to measure punctuality as an effort indicator.

Room assignment: Participants were randomly assigned to one of three training rooms on day 1. On day 2 they were randomly assigned one of the other two rooms, and on the third day they were assigned to the training room they had not yet attended.³⁰

Test scores: On each training day a test is administered to job trainees by the recruiter. These test comprehension of the materials taught during the training sessions and are used in hiring decisions. These are the primary measure used by the recruiter in making employment decisions. Refer to Appendix A for a detailed discussion on the determinants of hiring decisions.

Contribution records: Recruitment staff also recorded the verbal contributions made by job-trainees. These records enable me to construct a performance indicator of engagement. In the education literature similar measures of engagement have been used typically relying on teacher evaluations of student engagement (Dee and West, 2011; Friedrichs et al. 2004 reviews the education literature pertaining to student engagement). I also construct a subjective assessment of the quality of the contribution made. The quality scale is graded as *Good*, *Neutral* or *Bad*. In some cases, multiple members of the recruitment team were documenting these contributions. To eliminate double counting, I count a contribution only once assuming that it came within 5 minutes of a second contribution. In instances

³⁰ This ensures that all participants were in a different room on each training day. Although the same materials were taught simultaneously across training rooms, the recruiter felt it was necessary for the participants to be exposed to all the different trainers. All 3 training rooms were at the same venue. Participants were free to sit as they desired within the room they were assigned, their seating choice was recorded by the recruitment team. These records are used in later analysis.

where a contribution is recorded twice I use the lowest quality assessment if the rankings differ. The double counting allows me to assess the correlation in subjective assessments made. In 61.5 percent of the cases the two separate records were recorded as the same quality.³¹

Employment records: I obtain the employment records for the consenting job trainees.

Daily survey questionnaires: I supplement these administrative data sources with daily self-administered follow-up questionnaires. While respondents were completing these surveys all recruitment staff left the training venue. Research staff were available to address any questions. Participants were asked to drop their completed questionnaires in a sealed dropbox available at the venue. The daily questionnaire asked about time use, mental and physical health as well as employment attitudes and beliefs.

Table 1 Panel B presents survey data completion rates. There is some evidence of differential attrition with the follow-up questionnaires by treatment status.³² Only 83 percent of the participants who received no chance of an alternative job completed the follow-up survey questionnaire every day compared to 96 percent among those who were assigned a 100 percent chance of an alternative job. This difference of 13 percentage points is significant at the five percent level.³³ I primarily use the follow-up data to examine the impact of the outside options on self-reported effort as well as to shed light on the potential mechanism driving the performance results. The differential attrition is cause for concern as individuals assigned no chance of an outside option were the least likely to complete the survey questionnaires. It is possible then that those who did choose to complete the surveys are not representative of the group and the results may be biased. For example, for self-reported effort, individuals who put in the most effort during training may have been inclined to complete the surveys which would then overestimate the average effort of this group. I therefore implement weighted regressions that adjust for the attrition as well as implement bounding strategies as robustness checks.

4.3 Sample

The sample used in the analysis in this paper is the 268 consenting job trainees. All job trainees are men, aged 18 and older who have completed secondary schooling and actively sought work due to the

³¹ Additionally, in 26.5 cases, one record reports the contribution as *good* while the other rates it as *neutral*. In 9.64 percent of cases, one record reports the contribution as *neutral* and the other rates it as *bad*. Finally, in only two cases where the quality assessment differs one report assess it as *good* and the other as *bad*.

³² Completing the daily questionnaires was not a condition of receiving the alternative job.

³³ Differential completion rates are largest on day 1 and decline across time. By day 3 there is no differential attrition across treatment status for the follow-up survey completion. One possibility is that any resentment towards the research project due to being assigned a low probability of an alternative job declined over time. This is consistent with the happiness literature that shows that shocks to happiness are mitigated across time (Kimball, 2006) .

eligibility requirements of the recruiter.³⁴ Table 2 presents other summary statistics about the sample. On average, respondents are 25 years old, and 18 percent are married. Approximately 17.6 percent of the sample had at least one child.³⁵ Respondents are relatively well educated for Malawi, with an average of 13 years of education, a direct consequence of the hiring requirement that individuals have completed at least secondary schooling (12 years).³⁶ Respondents report earnings of approximately \$220 over the last 3 months.

Most of the men, 86.9 percent, report having worked previously. Although most men (86.1 percent) had worked at some point during the past 6 months they had only worked on average 2.7 months of the preceding 6 months.³⁷ Individuals who had previously worked were asked a series of questions about their three most recent jobs. For their most recent job 58 percent report competing for it, 26.8 percent report having had to write a test as part of the hiring process; almost 70 percent were required to attend an interview, and slightly more than half had required some job-training prior to employment.³⁸ In sum, the process is not atypical to the general hiring processes in this context.

5. Estimation Strategy

In this section, I discuss the key outcome variables of interest, then I present the main estimating equation. I discuss the validity of the random assignment in the sample. Lastly, I briefly discuss key alternative specifications implemented as robustness checks.

Key outcomes

To measure performance I rely on administrative records only. I use test scores from the training assessment tests as well as engagement in training. I use both quantity and quality measures of engagement in training: any contributions; cumulative number of contributions; total number of good contributions; total number of neutral contributions; and total number of bad contributions. I construct a performance index measure as a summary index of these performance indicators. The index constructed as the average of the normalized values of each of these measures (Kling, Liebman and Katz, 2007).

To measure effort I use both administrative data and survey data. From the administrative data I use the rich arrival data and construct measures of punctuality: ever late; always late; and minutes early or

³⁴ The sample is limited to only men older than 18 who had completed secondary schooling simply because those were the eligibility requirements of the recruiter.

³⁵ Although the fraction married and the fraction with at least one child are similar, these groups consist of different individuals – 19.6 percent of those who are married report having no children; while 16 percent of those with no children report not being married.

³⁶ Although this is relatively high for Malawi in general, it is not atypical for a representative sample of men in urban Malawi. From another survey (Chinkumba, et al. 2012) that randomly selected men the average years of schooling was 11.

³⁷ The sample used here is similar to the nationally representative integrated household survey sample in terms of key work related characteristics – for instance respondents in the IHS10/11 worked on average 5.6 months of the year which is similar to the 2.7 months (over the last 6 months) worked by respondents in the sample in this paper.

³⁸ Averages across the 3 most recent jobs are similar results not shown.

late. Using the survey data I use time use diaries to measure the number of hours spent studying training materials and the amount on leisure activities (watching television, listening to radio). Similar to the performance index, I also construct an effort index as a summary measure of effort. This is constructed by taking the average of the normalized values of the minutes arrived late, and time use variables.

Lastly, I examine employment outcomes using data from the recruiter regarding which respondents were hired by the recruiter.

Main specifications

The experimental design of the study permits a relatively straightforward analysis. To estimate the differential performance, effort and employment by treatment group, I estimate the following regression:

$$Y_i = \beta_1 T0_i + \beta_2 T1_i + \beta_3 T5_i + \beta_4 T50_i + \beta_5 T75_i + \beta_6 T100_i + X_i' \beta + \varepsilon_i \quad (1)$$

where: Y_i indicates job trainee i 's average performance or effort. The average for each indicator is constructed using data from three observations per individual. In the case, of missing data, the average is constructed from the observations available. The indicators $T0$, $T1$, $T5$, $T50$, $T75$ and $T100$ are binary variables equal to 1 if the individual received a 0, 1, 5, 50, 75 or 100-percent chance of an alternative job respectively and a 0 otherwise. Rather than assuming a linear relationship I specifically allow a flexible non-linear relationship between the probabilistic job guarantees and the outcome variables of interest. It is important to allow this relationship to be non-linear given the potential non-linearity introduced by the stress effect. Depending on the underlying baseline stress distribution and the size of the stress reduction induced from the probabilistic employment guarantees performance could be increasing, or decreasing in stress for all treatment groups, or decreasing for some and increasing for others. I measure the net effect (incentive effect + stress effect) of changes in employment risk on performance. I cannot disentangle the incentive and stress effects cleanly given the absence of biomarker data. While effort differences yield some insight into the size of the incentive effect one would need to impose structural assumptions on the effort-performance production function to disentangle the two effects.

Lastly, X is a vector of covariates including stratification cell fixed effects, ability score, previous experience with employer, age, and other background characteristics. To facilitate easier interpretation of the coefficients, I demean all control variables, so coefficients are interpretable as group means at the mean of all controls in the regression. Unlike many program evaluation randomized controlled trials there is no clear control group in my sample. Although individuals offered no outside option are akin to what individuals would face in the absence of this experiment, it is not a clean control group as they are allocated a poor draw for the purposes of the research.

My main comparison of interest is between those assigned no outside option ($T0$), and the certain employment guarantee ($T100$) that removes all risk from the job application process. While employment

risk is decreasing in the magnitude of the outside option, uncertainty of the alternative jobs is highest among those in the 50-percent group. This adds an additional layer of complexity in interpreting the results.

Given the random assignment of individuals to the different treatment groups, the identification assumption that the assignment to treatment is orthogonal to the error term should hold. One test of this assumption is to compare observable characteristics across the different treatment arms. Table 2 shows that the different treatment arms appear to be balanced when examining multiple baseline characteristics. In most cases, I cannot reject the null hypothesis that all the treatments jointly exhibit the same means. Similarly for most pair-wise comparisons I cannot reject that the groups exhibit the same means. As assignment was predetermined no strategic behavior was possible to change treatment status. Controls will be included in the results that follow but the results are robust to whether or not controls are included.

Alternative Specifications

I conduct a host of robustness checks. Firstly, for binary performance or effort indicators I use probit specifications. Second, I create a panel dataset using multiple observations per individual and conduct similar analysis as that presented in equation (1). However, when using multiple observations per person, it is important to adjust the standard errors appropriately given correlation in outcomes by individual, training room, and day of training. I discuss this in more detail in Section 6.3. Third, for any remaining concerns regarding imbalance of treatment assignment I present the analysis with and without controls, as well as construct a measure of the extent to which omitted variable bias would have to differ in unobservables relative to observables to explain away the differences in performance and effort (Altonji, 2005; and Miguel and Bellows, 2008). Fourth, I address missing data in the administrative records and differential attrition in survey data records. I use three strategies to address both of these concerns. The first approach I take is to follow Fitzgerald, Gottschalk and Moffit (1998) and present weighted results. I predict the probability of attrition. Using these predicted probabilities I construct propensity score weights for each individual. I then re-run the regressions using the computed weights. Second, I present conservative bounded results where I implement min-max bounds (Horowitz and Manski, 2000). First, I impute the maximum test score for all treatment groups except for the 100-percent treatment group where I impute the minimum test score. Then, I impute the minimum test score for all treatment groups except the 100-percent treatment group where I impute the maximum test score. Third, I restrict the sample to the 0 and 100-percent treatment groups and estimate Lee (2009) bounds on the average treatment effect of the 100 percent group relative to the 0-percent treatment group. I discuss the implications of each of these robustness checks for the performance and effort indicators in Section 6.3.

6. Results

This section presents the results. First, I show the performance results using administrative data including training test scores and measures of engagement in training. Second, I present and discuss the effort results using indicators both from administrative data (e.g. punctuality) and self-reported data (e.g. time spent studying training materials). Third, I present a broad set of robustness checks for the performance and effort results. Fourth, I discuss heterogeneity of the effects by baseline mental health status and ability. Fifth, I present the welfare implications of employment risk by examining the differences in employment. I conclude this section with a discussion of alternative explanations for the observed results.

6.1 Performance Indicators

I use two key indicators of performance in the analysis: performance on administered tests, and engagement of the job trainees in the training. To measure engagement in training, I examine differences across treatment group in the quantity and quality of verbal contributions. Recall that if a stress effect exists in this context then there exists an ambiguous prediction for performance indicators as outside options improve. The relative magnitude of the incentive and the magnitude and direction of the stress effects, will determine the prediction for performance as outside options change.

Administrative Training Tests

The most important assessment tool used by the recruiter for hiring decisions is the performance of the job trainees on the written tests administered during the job training. The correlation between performance on these tests and the probability of being hired by the recruiter is 0.60. The R-squared of a univariate regression of employment on the standardized average test score is 0.357 and the coefficient in this case is 0.225 (standard error is 0.0311). Therefore, for every additional standard deviation the individual is 31 percentage points more likely to be hired. The determinants of hiring are presented in and Appendix Table 1 and discussed in detail in Appendix A.

Figure 4 and Table 3 present the main test results using the average performance of the standardized test scores as the dependent variable. I find that job trainees assigned no outside option performed significantly worse than those assigned a 100 percent outside option. The magnitude of the difference ranges from 0.438 to 0.451 standard deviations depending on the set of controls used and is consistently significant at the 10 percent level. The magnitude of these effect sizes is quite large. Perhaps the best way of contextualizing the effects is comparing them to education interventions in developing countries that aim to impact test scores. Kremer and Holla (2008) review education randomized controlled trials conducted in developing countries. Test scores effect sizes from the 26 papers reviewed range between 0 and 0.46 standard deviations, with the exception of a technology assisted education

intervention in Nicaragua that found large effects of 1.5 standard deviations (Heyneman, 1981).³⁹ The median effect size from this review was 0.16 standard deviations. The observed test impacts in my setting are large.

There is also suggestive evidence in support of an increasing trend of performance as a function of unemployment risk. One exception to this trend is the relatively poor performance by those assigned the 75-percent chance of an alternative job. There is considerable variation in the performance of this group which is further explored when examining heterogeneity of the impacts in Section 6.4.

The finding that test performance is highest among those with the employment guarantee and lowest among those with the worst outside option suggests a large stress effect offsetting any gains in performance attributable to changes in effort.

Verbal Contributions

Next, I examine differential performance across treatment groups for verbal contributions made during the training sessions monitored by the recruitment team. In the education literature measures of student engagement have been used in assessing student performance. For example, student engagement is often assessed either through pupil self-reports or through teacher evaluations (Dee and West, 2011).⁴⁰ Appendix A discusses the importance engagement in employment decisions and highlights the importance of good quality engagement during training as a key predictor of employment in the current context.

I construct both a quantity and quality measure of student engagement. More than half the participants (67 percent) made a contribution at least once during the course of training. Individuals who engaged contributed 2.3 times on average. Approximately 46 percent of the contributions made were classified as *good*, 39 percent as *neutral* and 15 percent as *bad*.

The regression results that control for covariates and stratification cell fixed effects are presented in Table 4. The performance indicators used here aggregate performance across the three training days. Column 1 shows that job-trainees receiving the 100-percent chance of the alternative job were 11.2 percentage points more likely to make any type of verbal contribution. Probit results are broadly

³⁹ An alternative comparison to make is to compare the magnitude to randomized education interventions in the United States. A meta-analysis review article of randomized education interventions find mean effects sizes to be 0.33 standard deviations for elementary school, 0.5 for middle school, and 0.27 for high school interventions (Hill, et al., 2008).

⁴⁰ Classroom behavior in schools has also been shown to be important for labor market success (Segal, 2008, 2012, and forthcoming). I do have a similar measure of behavior to that used in this literature. However, in this setting training classroom behavior was not an important predictor for determining employment outcomes (See Appendix A). Recruitment staff recorded disruptions by participants during the training sessions. Disruptions include answering phone calls, exiting and re-entering the room, making jokes and chatting to other trainees, among other things. Almost half of the participants (47.1 percent) were recorded as being disruptive at some point during the training, the total average number of disruptions made was 2.11 conditional on making any disruption. In 47 percent of the cases the disruptive behavior relates to making noise, chatting with friends, banging on desks etc; in 42 percent of the cases the disruptive behavior refers to unnecessary moving around the room, or entering and exiting the training room; and in 11 percent of cases refers to participants answering the cellphone during training. Using this data I construct measures of whether the job-trainee was ever disruptive, the number of times he was disruptive and the number of each type of disruption. I do not observe substantive differences across treatment groups (See Appendix table 3).

consistent (Appendix Table 2). While these differences are quantitatively large they are not statistically significant. The total number of contributions is an alternative measure of the quantity of engagement. Table 4 column 2 shows that job-seekers' assigned a guaranteed outside option make 0.704 contributions more than those assigned no outside option.

A key dimension of engagement in determining employment decisions is the subjective quality assessment. Appendix A shows that making a good quality contribution impacts the probability of being hired. Job trainees assigned a 100-percent job probability are more likely to make good and neutral contributions relative to the other treatment groups. Similar to the test performance results, participants receiving the 100-percent job probability make 0.410 additional *good* contributions relative to those in the 0-percent job probability treatment group. This difference is statistically significant at the 10 percent level. In fact, individuals in the 0-percent group are the least likely compared to all groups to make a *good* contribution (only 0.528 contributions on average). This is consistent with the test performance results, which showed that individuals in the 0-percent group performed the worst on average, and those in the 100-percent treatment group performed the best (Table 4, Column 3). Similarly, job trainees assigned to the 100-percent treatment group are the most likely to make *neutral* contributions but the difference is not statistically significant ($p=0.127$).

Performance index

Although the performance indicators present similar results to address the issue of multiple inferences I create a performance index. This index is the mean of the normalized value of the average test score; and all the engagement measures (Kling, Liebman and Katz, 2007). Table 4 Column 6 presents these results. Individuals assigned no outside option perform 0.369 standard deviations worse than those assigned the guaranteed outside option. The difference is statistically significant at the 5 percent significance level. It is also interesting to look beyond the mean and consider the performance index distribution. The distribution of this index for the no outside option (T0) and the employment guarantee (T100) are presented in Figure 5. This figure shows that the performance distribution for those guaranteed outside employment is shifted quite significantly to the right. The p-value associated with a Kolmogorov distribution test of equality is 0.043.

In sum, I find that performance is highest among those assigned guaranteed outside options, and lowest among those with the poorest outside options. Differences are large in magnitude and often statistically significant. This suggests that at least in this context, a potential stress effect exists and is large and of the opposite sign as the incentive effect, resulting in overall lower performance among those with the greatest incentive to perform. Next, I turn to examine effort indicators to assess whether these results are driven by changes in effort.

6.2 Effort Indicators

In this section I examine effort indicators. Effort indicators should not be influenced by any stress reductions induced by the outside options assigned. Therefore, indicators should decline as outside options improve. In my case this implies individuals assigned higher outside options should exert the lowest levels of effort. To measure effort I use administrative data to measure punctuality, and self-report data to observe time use on study time on materials and leisure activities. I also combine these data to construct an effort index as a summary measure of effort.

Punctuality:

One potentially important indicator of effort is job trainee punctuality. On average, job trainees arrived 21 minutes prior to the beginning of the training start time. Approximately 16 percent arrived late on the first day, 11 percent on the second and only 5 percent on the final day (results not shown). Evidently, job trainees realized that their punctuality was being recorded and altered their behavior over time.⁴¹ Most participants are on time and in fact early, by approximately 25 minutes.

To measure punctuality I use three measures: ever late, always late, and average minutes early/late across the three training days. Table 5 shows that individuals assigned to the 100 percent treatment groups are 9.3 percentage points more likely to ever arrive late and 6.3 percentage points more likely to be always late compared to those assigned no outside option. These are large in magnitude but are not statistically significant ($p=0.34$; $p=0.271$). Probit results are broadly consistent (Appendix Table 2).

Table 5 Column 3 presents average minutes arrived early or late. I do not observe statistically significant differences in arrival times. To explore this further I use Kolmogorov-Smirnov distribution tests of equality. Taking this approach, I cannot reject at any reasonable level of significance that the distribution of arrival times on each day comparing any two treatment groups are different (Appendix Table 4).

Time use:

A second dimension of effort is self-reported effort. As part of the daily follow-up questionnaires individuals were administered a time use module. I focus on two key categories: time spent studying training materials; and leisure time spent listening to the radio/watching television. I construct the average hours spent on each of these activities across the three training days.

Table 5 column 4 presents the mean number of hours spent studying the training materials for each treatment group. Those with the guarantee of employment report spending the least amount of time studying the training materials, as much as 25 minutes less than those who received no chance of

⁴¹ An alternative explanation is that individuals learned across time how long it would take them to get to the venue as most relied on public transportation that can be very unreliable.

alternative employment.⁴² Moreover, Table 5 Column 5 indicates that individuals in the 100-percent chance treatment group are watching 53 minutes more television or listening to the radio. These results suggest individuals are substituting time spent studying for the training for leisure time.

Effort index

Similar to the performance index, I create an effort index. This index is the mean of the normalized value of the average minutes arrived early or late; number of hours spent studying the training materials and number of hours spent watching television and listening to the radio (Kling, Liebman and Katz, 2007). The results are presented in Table 5 Column 6. I find that those assigned no outside option exhibit 0.587 standard deviations less effort compared to those assigned a guaranteed outside option. The distribution of this index for the no outside option (T0) and the employment guarantee (T100) are presented in Figure 6. This figure shows that the effort distribution for those guaranteed outside employment is shifted to the left. The p-value associated with a Kolmogorov distribution test of equality is 0.005.

In sum, I find that effort indicators operate in the anticipated manner. Individuals assigned high outside options exert lower levels of effort whereas those assigned poor outside option exhibit higher effort. Therefore, the poorer performance among those with poor outside options is not driven by lower effort. Taken together these results suggest that stress may be a likely explanation or some other psychological consideration that operates in a similar way to stress offsets any gains from increases in effort exerted. Other potential explanations are discussed in Section 6.5.

6.3 Robustness

There are a number of specification checks that can be conducted. First, I discuss the robustness of the results to using multiple outcomes per individual and the appropriate standard errors required for this approach. Second, I discuss additional checks related to covariate imbalance across treatment status. Third, I attempt to address missing data and differential attrition.

Multiple outcomes per individual

For all performance and effort indicators presented I have multiple observations for each job-trainee. I can use the multiple observations for each job trainee and create a panel data set. In this case I estimate:

$$Y_{it} = \beta_1 T0 + \beta_2 T1 + \beta_3 T5 + \beta_4 T50 + \beta_5 T75 + \beta_6 T100 + X' \beta + T_t + \varepsilon_{it} \quad (2)$$

where: Y_{it} indicates job trainee i 's performance as measured by the recruiter at time t , and T_t captures fixed effects for the day or test on which the performance indicator is measured. Taking this

⁴² $(1.179 - 0.750) * 60$

approach however, has implications for the standard errors. Clustering the standard errors by job trainee when multiple outcomes for each job trainee are used accounts for correlation in outcomes within individual. However, this does not suffice because there are other systematic correlations that should be accounted for. These include correlation in outcomes at the day-room level, and correlation in outcomes at the day or test level. In the first case, there could be correlation in outcomes at the day level that is not specific to the training room. For example, if all individuals learn across time about the types of performance indicators monitored then there will be correlation within outcomes at the day level that is not related to the specific room to which they are assigned. In the second case, correlation in outcomes at the day-room level could arise due to external disturbances that affect the whole room. Individuals were assigned to different training rooms. Although all rooms were in relatively close proximity, disturbances in one room are not necessarily experienced by all rooms. Therefore there is likely to be correlation in outcomes at the day-room level. To address these concerns I use two-way clustering to adjust for both individual and day-room correlations simultaneously (Cameron, Gelbach, and Miller, 2008). This sufficiently accounts for individual and day-room level correlations. Day or test correlations are subsumed in the day-room adjustment. I discuss the results of adopting this approach for the performance and effort indicators below.

Performance Indicators: Appendix Table 5 presents these results. I use the standard specification that includes stratification cell fixed effects and covariates as well as test fixed effects. For the administrative tests I use the standardized score on each test as a separate outcome; thus, there are three observations per individual. I find smaller but still large differences between the 0-percent and 100-percent treatment groups of 0.3 standard deviations (Appendix Table 5 Column 1). This difference is statistically significant at the 10 percent level and is consistent with the prior results.⁴³

For engagement indicators, I also find somewhat smaller differences than that observed using the aggregate indicators (Appendix Table 5 Columns 2 – 6). However, again these results are consistent with the aggregate findings presented earlier.

Effort Indicators: Similarly, Appendix Table 6 presents panel data results using the set of effort indicators. For punctuality, I use whether or not the respondent is late and the minutes arrived early or late. I find smaller effect sizes but qualitatively similar results as before. The difference between those assigned no outside option and a guarantee (T100) remain statistically insignificant (Appendix Table 6 Columns 1 and 2).

⁴³ The coefficients estimated in this case are somewhat smaller than the case where the average test performance. This is driven by the fact that the estimated effects are different across tests. For test 1, the observed effect is small and insignificant, while the estimated differences are large (approximately 0.4 standard deviations) for test 2 and test 3.

Reported effort results are also qualitatively similar to the aggregate results. Respondents assigned the guaranteed outside option reduce study time by 26.5 minutes and increase time spent watching television and listening to the radio by 51.6 minutes (Appendix Table 6 Columns 3 and 4).

Covariate imbalance specification checks:

Another specification check relates to potential violations of the identification assumption that treatment assignment is uncorrelated with the error term. Although treatment was randomly assigned and covariates appear to be balanced at baseline, given the relatively small sample there may still be persistent concerns regarding omitted variable bias in unobservables. Adding covariates do not influence the results substantively further suggesting that imbalance is not a serious concern (Appendix Tables 7 and 8). However, as an additional specification check I construct a ratio that assesses the extent of omitted variable bias that would be required to explain away the results (Altonji et al., 2005 and Bellows and Miguel, 2008). Appendix Table 9 presents the ratios for each of the performance and effort indicators for which significant difference between those assigned no outside option and a guaranteed outside option exist. The ratio measures the extent to which selection on unobservables would need to exceed selection on observables to explain away the coefficient. Therefore, a larger ratio implies that the relative omitted variable bias from unobservables relative to observables is greater, and therefore estimated effects are less likely to be explained away.

Performance indicators: For the case of this key performance results, the ratio is 68 which is considerably high. This ratio means that the selection on unobservables would have to be 68 times greater than selection based on observables controlled for. For engagement indicators, the ratios are somewhat lower around 1.5 to 1.8.

Effort indicators: Similarly, the effort indicators suggest that selection on unobservable would have to be much larger than the selection based on observables ranging between 7 and 9.7.

Differential Attrition and Missing Data

For the administrative data there are missing values for some of the performance indicators. For example, there is a subset of test scores that are missing (5.2 percent). These are missing for a variety of reasons: missing test scores, illegible or incorrect employment IDs on submitted tests; and some individuals did not write all tests.⁴⁴ Given that the participation rates in training are not differential across treatment groups we would not expect there to be significant implications of the missing data on the results. I implement various methods as a robustness check. Also as noted in Section 4.1 and presented in Table 1 Panel B, there is differential attrition with respect to survey data completion rates. Differential

⁴⁴ Recall participation rates were not 100 percent across all training days, Table 1.

attrition by treatment group may bias the observed results where survey data was used. Conducting robustness checks in this case is particularly important.

I use the same strategies to address both the missing data and differential attrition concerns. First, I present weighted results. I largely follow Fitzgerald, Gottschalk and Moffit (1998). I predict the probability of attrition. Using these predicted probabilities I construct propensity score weights for each individual. I then rerun the regressions using the computed weights. Second, I present conservative bounded results where I implement min-max bounds (Horowitz and Manski, 2000). First, I impute the maximum test score for all treatment groups except for the 100-percent treatment group where I impute the minimum test score. In a second regression, I impute the minimum test score for all treatment groups except the 100-percent treatment group where I impute the maximum test score. Lastly, I restrict the sample to the 0 and 100-percent treatment groups and estimate Lee (2009) bounds on the average treatment effect of the 100 percent group relative to the 0-percent treatment group. I discuss the implications of each of these robustness checks for the performance and effort indicators.

Performance Indicators: Appendix Table 10 presents these results. Columns 1, 4, 7 and 10 present the weighted regressions. Columns 2, 5, 8 and 11 present a conservative minimum bound, and Columns 3,6, 9 and 12 present a conservative maximum bound. Appendix Table 8 Panel A presents the Lee bounds. For all performance indicators both test results and engagement in training the weighted results are very similar to the main results.

Using the conservative min-max bounds, the differential performance on tests between individuals receiving a 0 and those receiving a 100-percent chance of an alternative job is no longer statistically significant. However, the differential effect remains positive albeit considerably smaller, only 0.067 standard deviations (Appendix Table 10, Col 2).

The Lee bounds (2009) for the average test performance results are presented in Table 11. In this case I restrict the analysis to only the 0 and 100-percent treatment groups and estimate a lower bound of the performance improvement of the T100 group (compared to the T0 group) at 0.346 standard deviations (p-value=0.154); and the upper bound is 0.492 (p-value=0.054).

For engagement in training indicators, using the conservative bounding approach does not affect the direction of the coefficients although the magnitude of the differences is muted, and for the number of good contributions the difference between T0 and T100 is no longer statistically significant at the 10 percent level (p=0.249) . The Lee bounds (2009) for the key engagement variable, the number of good contributions, comparing those with the guaranteed outside options to those assigned no outside option are 0.413 (p-value=0.192) and 0.5092 (p-value=0.099).

Effort Indicators: Appendix Table 12 presents the robustness checks for the effort indicators. Columns 1, 4, and 7 present the weighted regressions. Columns 2, 5, and 8 present a conservative

minimum bound, and Columns 3,6, and 9 present a conservative maximum bound. Lee Bounds are presented in Appendix Table 11 Panel B. In all cases, including the time use indicators the results discussed are robust. Even using the most conservative bounds for the time use results, the difference between the amount of time spent between T0 and T100 remains statistically significant at the 5 percent significance level and sizeable. Those assigned the job guarantee (T100) spend 19 minutes less studying the training materials, and 41 minutes less watching television/listening to the radio. The Lee bounds are particularly important in the case of the time use data. The Lee bounds show that those assigned a guaranteed outside option study the training materials less, and watch more television. The upper and lower bounds are statistically significant and consistently show large differences between those assigned the job guarantee (T100) and those assigned no additional probability of outside employment (T0).

In sum, the results are robust to a number of alternative specifications. That is I consistently find that performance is highest among those with guaranteed outside options, and lowest among those assigned no outside option. However, effort is highest among those assigned no outside option, and lowest among those with the guaranteed outside options.

6.4 Heterogeneity

Stress responses are widely considered to be individualistic (Hobfoll, 2004). There is no reason why one would expect this to be any different within the context of unemployment uncertainty induced stress responses. Understanding heterogeneity of impacts is thus important for policy considerations.

In this context, heterogeneity may arise for a number of reasons. It is useful to distinguish between how the incentive and stress effects vary given heterogeneity among agents. The incentive effect may differ across job-trainees. If agents face different cost of effort functions ($c(e)$). There are two key sources in which heterogeneity of the stress effect could arise. First, the distribution of baseline stress across individuals will result in heterogeneity of the stress response by baseline stress level. For example, compare individuals at t'_0 and t''_0 on Figure 1a. A reduction in stress of amount s results in differential changes in performance for these individuals. Second, even among individuals with the same baseline stress level, extensive research shows that individuals differ in their ability to cope with stress (Kirschbaum et al. 1995; Ditzen et al., 2008; Fiocco, Jooper and Lupien, 2007). Therefore, the same change in employment risk may yield differential stress reductions across individuals. For example, consider two different individuals at t'_0 in Figure 1b, for one individual the employment guarantee may reduce stress by s for a second individual it may reduce stress by s' resulting in different implications for performance. Therefore, there are multiple sources of potential heterogeneity.

I focus on exploring the heterogeneity of the observed impacts by mental health status. Individuals with better mental health may be more able to cope when faced with employment uncertainty and in my case may incur a smaller benefit from the stress reduction of the employment guarantee. However, given that mental health and stress are highly correlated, individuals with better mental health may exhibit lower baseline stress levels and therefore may benefit more from the stress reduction due to the concavity of the Yerkes-Dodson curve. Therefore, it is ambiguous how effects may differ across groups. Given limited power in my sample, and the unavailability of reliable medical biomarkers measuring stress (e.g. cortisol), the results I present are suggestive rather than conclusive.

To measure mental health status I use the SF-36 instrument that maps into 8 health indicators four pertaining to mental health as well as a composite mental health summary measure; and four to physical health (Ware and Sherborne, 1992; Ware, Kosinski, and Keller, 1994 and 1995). This instrument has been widely used worldwide and validated in other African countries (Wagner et al., 1999; Wyss et al. 1999). The mental health composite measure has been shown to perform as well or better than the individual mental health indices in predicting mental health problems (Ware et al, 1995) as such I use the composite index. The mental health index ranges from 0 to 100 where a higher number represents better mental health. In the sample, I observe a range of 39 to 81.

Table 6 presents the results. First, on average individuals exhibiting poorer mental health perform worse on average (even when one controls for ability) than those with better mental health. Second, across the mental health distribution as the probability of the outside option increases so too does the individuals' performance. This result maps directly to the downward sloping portion of the Yerkes-Dodson law. The third key finding is suggestive rather than conclusive. There is weak evidence suggesting that the gap between the performance of individuals with better mental health (compared to those with poorer mental health) is larger when assigned a higher outside option. To illustrate this, consider the following test: $100\% + 100\% * MH = 0\% + 0\% * MH$. The p-value associated with this test is 0.099. However, this result is not robust, for example using a binary indicator of "good" mental health, the slopes are no longer statistically significantly different ($p=0.021$).

Other heterogeneous treatment effects

Given that I stratified treatment assignment by ability and prior work experience these are two obvious dimensions to explore heterogeneity. Given that less than 10 percent of the sample had prior work experience with the recruiter and these 26 individuals are split across six treatment groups. However, for ability I find that independent of ability, performance is higher when individuals are assigned better outside options. Interestingly, the results do not suggest that the outside options operate differently depending on ability. There is considerably variation in the 75-percent treatment group. Job trainees within this group performed significantly differently depending on their ability. That is, the high

ability types performed well, while the low ability types performed exceptionally poorly; on average resulting in low performance in this group.

6.5 Welfare Implications: Employment

It is important to assess the welfare implications of the observed performance response to employment risk. To do this, I examine employment outcomes.⁴⁵ As discussed in Appendix A, while the performance indicators do a relatively good job of predicting performance there is still a large unobservable component determining employment outcomes. Therefore, while one might expect an employment response it depends on the role of the large unobserved component.

Figure 7 depicts the share of job trainees hired by the recruiter by treatment group. About 25 percent of trainees in the 75 and 100 percent chance of an alternative job groups were offered employment by the recruiter.⁴⁶ Thirteen percent of individuals who received no chance of an alternative job were hired by the recruiter. Those individuals that received a 50-percent chance of an alternative job were the least likely of all treatment groups to be hired by the recruiter – only 11 percent of these participants were hired by the recruiter, making them half as likely to be hired relative to those who knew they had high chances of alternative employment.⁴⁷

Table 7 Panel A presents the OLS results for employment as depicted in Figure 7. Table 7 Panel B presents the probit results. The marginal effects reported are the partial derivatives evaluated at the mean of the covariates. Given the performance indicator results it seems reasonable to use the 100-percent treatment group as the omitted category. The results are similar in the full sample as compared to a restricted sample that consists only of trainees who attended training every day. Individuals in the 0, 5, and 50 percent chance of alternative work treatment groups are less likely to be employed by the recruiter by between 9 to 11 percentage points. These impacts are statistically significant and are large in magnitude

⁴⁵ There are a number of on-the-job performance measures that can be constructed, ie. performance on the job when successfully hired and working for the recruiter. On-the-job performance was not measured during the alternative jobs however the long term impacts of being assigned an alternative job on future employment and wages are presented in Godlonton (2012). Recall that job trainees were hired as interviewers for a health survey. Therefore to measure on-the-job performance one can use survey data from the health survey. For example, one can measure the number of skip rules incorrectly followed; and the number of inconsistencies by interviewer. For these indicators there is little difference by treatment group. Also, one could construct the number of interviews conducted per day by interviewer; or the amount of time spent interviewing during the day. However, these indicators are not a clean measure of performance because supervisors shift interviewers to optimize fieldwork. For example, good interviewers may be given hard to find respondents and so the amount of time worked and the number of interviews conducted per day are not good indicators of performance. Rather, a summary measure of performance that may be more informative is whether the recruiter offers an individual a renewed short term employment contract. The recruiter had three waves of contract renewals. In general, the likelihood individuals in the 75 and 100 percent groups are hired in each subsequent round is about twice the employment rates of the other groups. Differences are often not statistically significant due to limited power.

⁴⁶ Note that only one participant who was offered a position by the recruiter opted not to take the job, as such the offer of a job and the record of who got hired are approximately the same.

as they translate into a 50 percent lower chance they will be hired compared to those in the 100-percent treatment group.

Two other interesting results are worth noting. First, individuals assigned to the 75-percent treatment group are no less likely than those in the 100-percent group to be hired by the recruiter. Recall, that on average that this group did not perform well on the written tests but there is considerable heterogeneity in their performance both by mental health status and ability (See Section 6.4). Second, there is suggestive evidence that the individuals in the 1-percent treatment group are more likely to be recruited than the 0-percent treatment group. Although there is insufficient power in the current sample to determine this it is interesting to note that a small change potentially has large impacts.

Potential Confounders for Employment Results

One concern with the employment results is potential strategic behavior by the recruiter in their hiring decision in response to the treatment assignment. However, the recruitment team had no knowledge of the specific alternative job probability assigned to each participant. The only way in which the recruitment staff would know of a trainees' alternative job probability would be if that participant directly informed a recruiter. Even if this did occur, although anecdotally there are no reports of this occurring, one would expect that it would bias the results in favor of having higher employment rates for those assigned lower alternative job probabilities. Given that I observe lower employment rates in this group, if such strategic behavior had been present my results are a downward biased estimate.

Another concern is that assuming that the recruiter did learn a trainee's alternative job probability they may have (incorrectly) inferred that a high probability of an alternative job implied something about the ability of the trainee. The recruiter has worked in implementing randomized controlled trials for a number of years within Malawi and understands the concept of random assignment. Moreover, the recruiter handed over the ability scores precisely for the random assignment of treatments to be stratified across baseline. As such, strategic behavior from the recruiter's perspective regarding their hiring decisions based on the random assignment is unlikely whether or not the trainees tried to lobby in any particular way.

6.6 Alternative Explanations

There are a number of alternative theories that might explain the performance and effort results presented in Sections 6.1 and 6.2. Some possibilities include: External job search; Gift Exchange; Stereotype-threat; Efficiency-wage hypothesis; Alternative psychological considerations. I discuss each of these in turn.

External job-search

One potential behavioral response in this setting is that job-trainees assigned poor outside options reduced their participation in training opting to rather increase external job search effort. Recall that

individuals were paid for participation during the training, and the wage rates paid for training are relatively competitive in this environment. While there is some evidence supporting lower attendance of individuals in the 0-percent treatment group relative to the 100-percent treatment group (Table 8 Column 1), the difference is neither large (4 percentage points) nor statistically significant (although p-value is 0.147).

Job search among those who attended training would be difficult. Participants spent approximately 8 hours in training per day, and report another 1.6 hours in transit, 6.8 hours sleeping (on average). Moreover, the job training period was conducted over a relatively short time frame, delaying job search by 3 days would not be seen to be costly.

Gift exchange

A second alternative explanation might be some model of reciprocity. The gift exchange hypothesis presented in seminal work by Akerlof (1982) and built upon in the work by Akerlof and Yellen (1988 and 1990) relies on the key assumption that there exists a positive relationship between wages and worker effort. This relationship explains higher than market clearing prices where workers reciprocate higher wages with more effort. There exists substantive lab experimental evidence in support of the gift exchange model. Fehr, Kirchsteiger and Riedl (1993) provide some of the first evidence, and Fehr and Gaechter (2000) provide a survey of the reciprocity literature more generally. Recently, Gneezy and List (2006) tested the gift exchange model in the field and find only short term evidence of the gift exchange model. They find that offering workers higher wages led to increased effort exerted only in the first couple of hours, after which positive reciprocity was not observed.

In my setting job trainees may feel rewarded when allocated a high outside option and may exert more effort to reciprocate and in turn perform better. While the performance results are consistent with this prediction as I find that individuals assigned high outside options performed considerably better than those assigned poor outside options I do not observe increased effort.

In sum, although a gift exchange hypothesis yields similar performance predictions for gift exchange to be the key driving mechanism effort indicators should also increase as outside options increase and I find the opposite results for effort indicators.

Efficiency Wage Hypothesis

Another framework that would also yield similar predictions for the performance results is the efficiency wage hypothesis. This hypothesis has been extensively researched (Liebenstien, 1957; Stiglitz, 1976; Deolalikar, 1988). Improved nutritional intake improves both physical and mental well-being which translates into increased productivity.

In the current setting, individuals that were guaranteed an alternative job may have been able to borrow against this guarantee and improve their nutritional intake. The results in this paper may be

attributable to better nutrition over this short period. While a comprehensive caloric intake daily roster was not administered, I do collect information on daily expenditures on food. This includes expenses on food consumed at home, and away from home. Table 8 Columns 2 and 3 present these results. I find that food expenditures are relatively consistent across the treatment groups. I do not observe statistically significant differences between expenditures between the 0-percent and 100-percent treatment groups. When accounting for the differential attrition (Appendix Tables 11 and 13) using weighted and conservative bounds I still cannot reject that the 0-percent and 100-percent treatment groups spent differential amounts on food either on groceries or by eating out.

Given these findings, it is unlikely that the key driver for the results observed is driven by nutritional intake changes.

Stereotype threat

Another potential explanation has its origins in psychology. Steele (1997) defines stereotype threat as: “the event of a negative stereotype about a group to which one belongs becoming self-relevant, usually as a plausible interpretation for something one is doing, for an experience one is having, or for a situation one is in, that has relevance to one's self-definition. It happens when one is in the field of the stereotype, what Cross (1991) called a "spotlight anxiety" (p. 195), such that one can be judged or treated in terms of a racial stereotype.” A substantive literature exists addressing stereotype threat and test performance (Spencer et al., 1997, Maas and Cadinu, 2003; Inzlicht and Ben Zeev, 2000; Steele and Aronson, 1995).

In my setting, job trainees may perceive their outside option as a signal of their ability. Although assignment does not reveal information regarding an individuals’ ability or performance relative to the other participants, job trainees may still believe that assignment is correlated with their ability. In this case, performance of individuals could be driven by self-fulfilling perceptions of their own ability. This hypothesis predicts that individuals assigned low outside options are likely to perform worse, consistent with my findings.

To test whether this mechanism driving force of the performance results I examine the extent to which job trainees’ updated their beliefs about getting the recruiter’s job by treatment status. Respondents were asked “What percentage chance do you think you have of getting one of the available positions for the RECRUITER’S PROJECT?” with the following options: No chance of getting a job; Less than 25 percent; Between 25 and 50 percent; 50 percent; Between 50 and 75 percent; Between 75 and 99 percent; and Certain about employment with recruiter. To create a measure of the likelihood of employment I assign the mid-point to categories that are brackets and creating a continuous variable. Using this variable we observe that individuals in the 75-percent treatment group did have significantly better perceptions about their chances of getting a recruiter’s job (Table 8, Column 5) compared to all other groups.

Another way to compare this outcome data is to look at the distribution of perceptions among the different treatment groups across time. Using Kolmogorov-Smirnov distribution tests of equality I find that the distribution of perceptions using this measure are not different when comparing those assigned no outside option and those assigned a guaranteed outside option. In fact, with the exception of the distribution of the 50-percent probability group all of the pairwise distribution comparisons between the various treatment groups are not statistically significant. Given the large number of pairwise comparisons it is perhaps ill-advised to read too much into the distribution of the 50 percent treatment group being distinct from the 0, 5 and 75 percent chance distributions of beliefs. These results are presented in Appendix Table 14.

These results do not however, suggest that individuals were not updating their beliefs as they underwent the recruitment process, just that individuals did not update their beliefs differentially by treatment status.

However, again the key performance result is observed between individuals in the 0-percent treatment group and those in the 100-percent treatment group does not seem to be driven by stereotype threat because there are not large differences in these two groups' perceptions of their chance of being recruited.

Other psychological considerations

Ideally, to determine whether the *stress effect* really is the driver of the observed performance effects biomarker data collection (e.g. cortisol) would have been optimal. Unfortunately due to budgetary and logistical restrictions this was not possible. However, in a pilot conducted heart rate readings were taken prior to the announcement of the job probabilities and then at the end of the training around the same time of day. Individuals assigned a guaranteed outside option experienced a 6.4 point greater decline in their heart rate ($se=3.25$) compared to those assigned a 1 percent outside option (in the pilot the “no outside option” did not exist). This is suggestive evidence that stress was reduced among those assigned the job guarantee. While biomarker data collection would yield insight into the presence of a biological stress response it would not address outstanding questions regarding how the stress acts to inhibit performance.

Psychologists extensively study the precise mechanisms driving sub-optimal performance. Many factors have been identified in psychological research that all contribute to sub-optimal performance including: the mere presence of an audience, public speaking, public announcements about performance (Baumeister and Showers 1986; and Beilock, 2010). The psychological literature moves beyond identifying factors that affect performance in this way and examine precise mechanisms related to how working memory is affected that leads to the sub-optimal performance. In my setting, it could be that job-seekers assigned the low outside option overthink their performance whereby paying too much attention

actually becomes counterproductive (Cochran, et al. 1999; Beilock et al, 2002). Another possibility is that individuals assigned no outside option reflect on the saliency of their likely continued unemployment which results in an increase in distracting thoughts related to worrying preventing them to focus attention on the important information (Hayes, Hirsh and Matthews, 2008). What the precise mechanism is cannot be determined in this study.

7. Conclusion

Jobs are increasingly scarce and billions of workers are either out of work, underemployed, or face uncertain future employment prospects. With a growing pool of applicants for any particular position, employers have to rely on various screening tools in recruitment processes. However, the design of these processes has important welfare implications depending on who is favored under different systems. Understanding how employment risk can affect performance is important in this context.

I find that performance is highest and effort is lowest among those with the lowest employment risk, and performance is lowest and effort highest among those facing the highest employment risk. Job trainees perform better both on administrative tests testing materials taught during training, but also are more actively engaged in the recruitment process. However, these performance enhancements are not driven by changes in effort. I find effort is lowest among those assigned the best outside options. In other words, I observe that reducing the employment risk by virtue of an employment guarantee enables semi-skilled workers in very uncertain labor markets to increase their efficacy of effort resulting in an average performance improvement.

My findings, are consistent with prior laboratory evidence (Ariely et al. 2009) in the sense that performance is negatively correlated with risk and effort is positively correlated with risk. My contributions go beyond affirming this finding, however. I extend the experiment from the risk associated with wage incentives to study employment risk, a distinct though clearly related construct with potentially larger welfare consequences. I also extend the literature from the lab to the field. The variation in risk in laboratory studies is artificial and over windfall income, but in my setting, the variation is over risk in securing real, meaningful employment equivalent to that subjects have chosen to apply for through a competitive and arduous process. To my knowledge, no evidence in real-world settings has illustrated the link between risk, performance, and effort, and as noted by Kamenica (2012), whether the previous findings will extend beyond the laboratory was previously unknown. Additionally, I collect a rich series of baseline and outcome data in order to incorporate an important strand of the psychology literature, which studies the mechanisms through which risk and uncertainty affect behavior. Many previous studies in economics have only identified the reduced-form relationship between uncertainty or risk and

performance, though Angelucci et al. (2012) measures cortisol in a laboratory study of how stress affects entrepreneurship. The data I collect allow me to rule out alternative mechanisms, which I discuss in detail later in the paper. I was unable to measure cortisol but do have data about mental health from the SF-36, as well as heart rate (a measure of arousal) from a smaller pilot study. Finally, my study speaks to the growing literature about the effect of high-stakes testing. My results suggest that the same settings that disadvantage some individuals in educational settings are also likely to affect them when seeking jobs.

The results observed are important as they suggest a potential mechanism through which unemployment is self-perpetuating. Stress deriving from uncertainty about employment lowers performance on the job or in job search activities. Therefore, unemployment and the stress related to it become a negative cycle sustained by stress-induced performance reductions. Such a cycle would then serve to perpetuate inequality both at the micro- and at a macro- economic level.

The negative relationship between risk and performance is likely driven by stress responses. It does not seem to be driven by models of reciprocity, self-fulfilling expectations, or the nutritional-wage hypothesis. I cannot rule out that some other psychological consideration that operates similar to stress is driving the result. Moreover, I cannot determine the precise psychological mechanism through which stress operates. Future research could build on this to further unpack the underlying mechanism through which risk and performance are negatively correlated.

This figure presents the estimated group means controlling for covariates and stratification cell fixed effects.

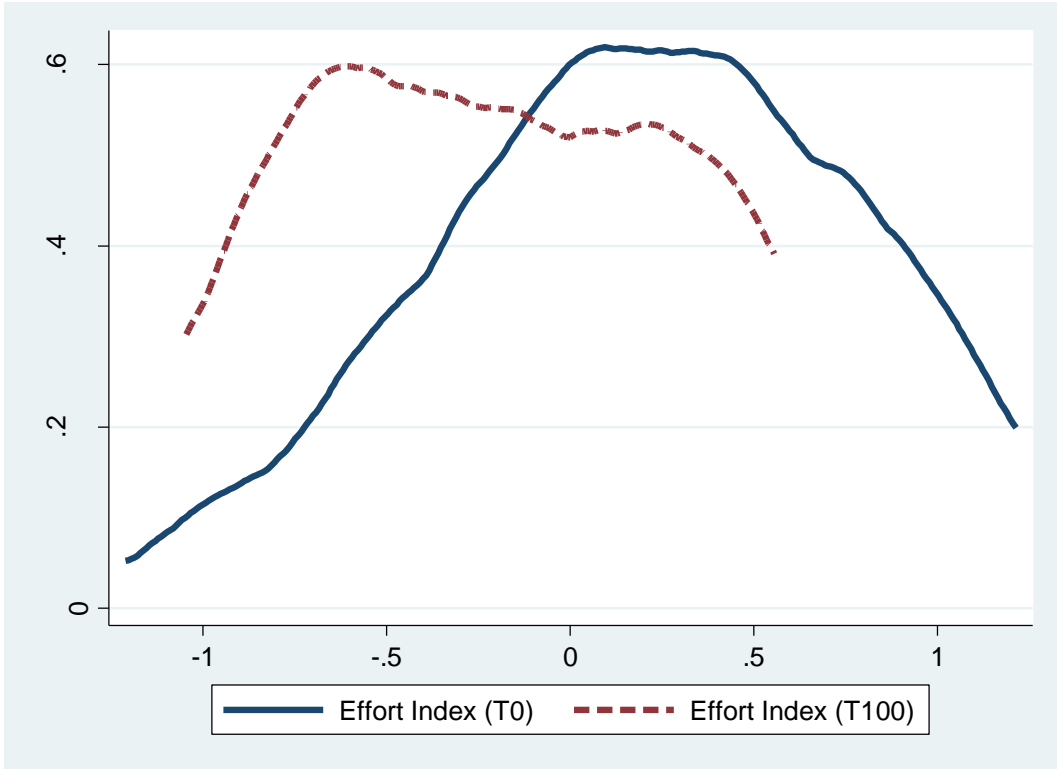

Figure 5a: Effort Index Distributions

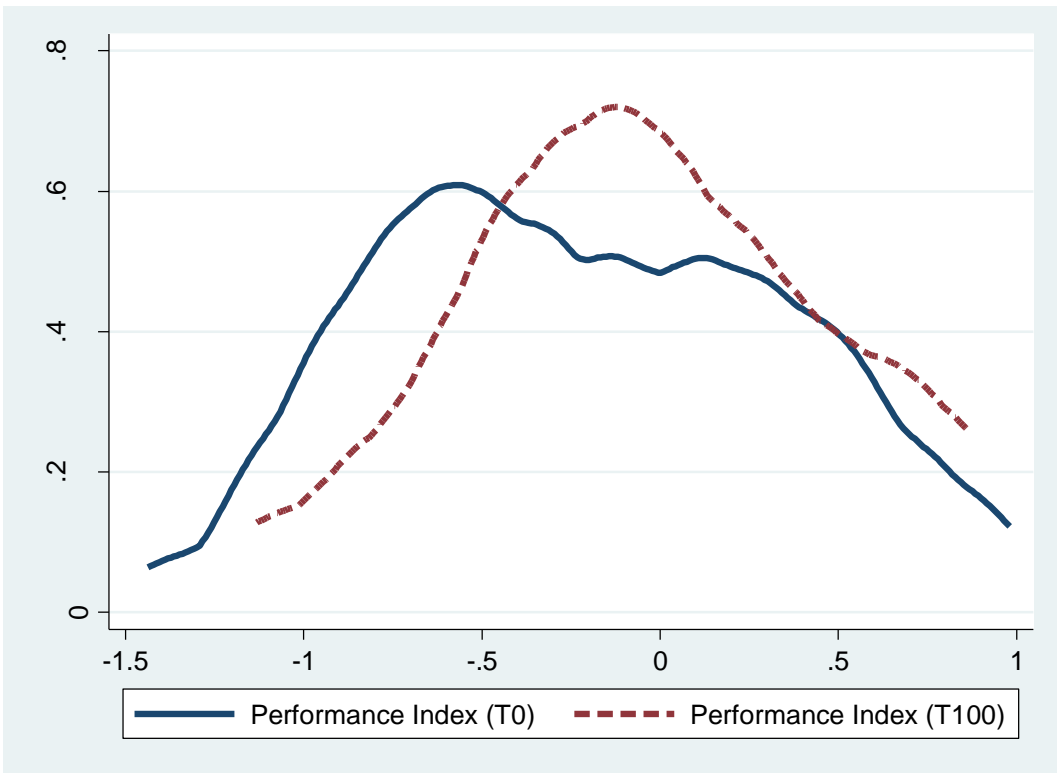

Figure 6: Performance Index Distribution

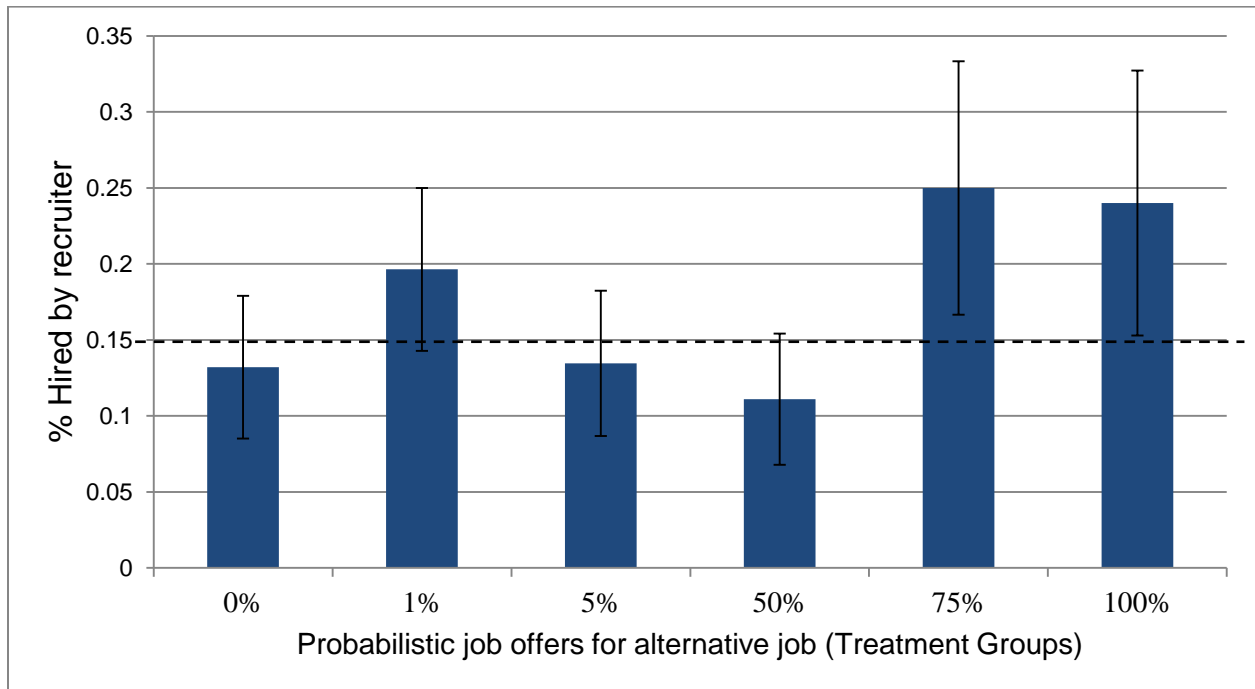

Figure 7: Fraction employed by recruiter by treatment group

The dotted line represents the fraction that would have been hired in the absence of the experiment.

Appendix A: Determinants of hiring decision using administrative data

In making hiring decisions the recruiter took a number of factors into account. As discussed above the recruiter conducted multiple tests to ensure that trainee participants paid attention and to ensure an objective measure of assessment was available to them. No participants were hired that had a standardized test score (using the composite test measure) less than 0.05. All participants that had a standardized test score greater than 1.3 were hired. As such although performing well on the test is a key factor in the hiring decision, 72 percent of the group that were hired had test scores in a region where that was not a sufficient determining factor. That is, performing well on the test was a necessary condition to get hired. It was not however a sufficient condition for those participants with a standardized test score between 0.05 and 1.3.

Appendix Table 2 presents the determinants of the hiring decision making process of the recruiter. This shows that the standardized test score is an important determinant of whether the person gets hired - a 1 standard deviation increase in the composite test score results in 9.7 percentage point increase in the likelihood that the individual is hired. Other key indicators that were measured by the recruiter include the punctuality, contributions and disruptions. Given Appendix Figure 1, it suggests that any alternative measures of evaluating performance should be interacted with the test score.

Punctuality appears to have little impact on the hiring decision. Interestingly for those individuals that do come late, this seems to increase their chances of employment if they have higher standardized tests scores (although the magnitude is small – for every additional minute late they are 0.3 percentage points more likely to be hired if they have a standardized test score of 1) (Column 2 of Appendix Table 2). Appendix Table 2 also shows that for those performing well (in terms of their standardized test score), making “good” and “neutral” contributions during the training sessions increased the probability that they were hired. In such a large hiring process being noticed in a good way mattered for those participants that performed well but not exceptionally well. Lastly, Column 4 of Appendix Table 2 also includes measures for disruptions made by participants during the training. This appears not to have any significant impact on the hiring decision making process as the magnitude of the coefficients are small and statistically insignificant.

Evidently, the most significant factor taken into account by the recruiter in its hiring decisions was the performance of participants on the written tests. However, there is evidence that other performance indicators were also taken into account – in particular whether or not the applicant made a “good” contribution to the discussion

Table 1: Sample and Attrition

| Panel A: Sample (pre-treatment): Treatment Assignment | | | | | | | | |
|--|----------|------------|-----------|-----------|-----------|------------|------------|-------------|
| | | All | 0% | 1% | 5% | 50% | 75% | 100% |

| 75% and 100% | 0.936 | | . | 0.315 | 0.346 |

Notes:

The sample frame consists of 278 participants that were short listed for training by the recruiter.

Panel A shows intended and actual assignment of the job probabilities. These distributions differ due to 10 participants that opted out of the research study (prior to learning their treatment status) or opted out of the training prior to the commencement of training. The main sample used in this paper consists of 268 individuals.

Panel B presents average participation rates in training and survey data completion rates by treatment group. A partial set of p-values from pair-wise comparisons of treatment group means are presented. All those that are not presented have p-values greater than 0.10. The full set of results is available on request.

Table 2: Summary Statistics and Balancing Tests

| Baseline Characteristics: | Treatment Assignment | | | | | | | F-stat ¹ | # pairwise differences ² |
|---|----------------------|---------------------|---------------------|---------------------|---------------------|---------------------|---------------------|---------------------|-------------------------------------|

| <i>p-values associated with F-tests for joint significance of covariates³:</i> | | | | | | | | | |
| Compared to all other groups | | 0.175 | 0.395 | 0.400 | 0.060 | 0.146 | 0.223 | | |
| Compared to 0% | | | 0.006 | 0.397 | 0.098 | 0.210 | 0.014 | | |
| Compared to 1% | | | | 0.782 | 0.009 | 0.559 | 0.147 | | |
| Compared to 5% | | | | | 0.468 | 0.405 | 0.772 | | |
| Compared to 50% | | | | | | 0.078 | 0.025 | | |
| Compared to 75% | | | | | | | 0.004 | | |

Notes:

The table reports group means or proportions (where applicable, e.g. married). Standard deviations are reported in parentheses. The main sample of 268 participants is used here. Data from both the baseline self-administered questionnaire and data collected by the recruiter from the screening assessment test both of which precede treatment assignment are used. Income is measured in USD and includes all self-reported income from the last 3 months including the following explicit categories: Farming; Ganyu (piece-work); Formal employment; Own business; Remittances; Pension; and Other. The ability scores are a composite measure of literacy and numeracy scores and are presented in standardized units. See Figures 3a, 3b and 3c for the distribution of these scores.

¹ These p-values correspond to the joint F-test of the means/proportions being equal across all treatment groups.

² This refers to the number of pairwise comparisons between treatment groups that are statistically significant at the 5 percent level. A total of 15 comparisons are made for each variable.

³ These F-statistics report the p-value from the joint F-test for whether all the covariates listed are jointly equal in predicting assignment to the treatment group.

Table 3: Average performance on training tests by treatment group

| | Average training test score | | |
|------------------------------------|-----------------------------|-------------------|-------------------|
| | (1) | (2) | (3) |
| 0% Job Guarantee | -0.176 [0.147] | -0.19 [0.142] | -0.177 [0.142] |

| Includes controls? | No | No | Yes |
| <i>p-values of F-tests:</i> | | | |
| 0% and 100% | 0.076 | 0.069 | 0.073 |

Notes:

This table presents mean performance on the recruiter administered training tests by treatment group. The average standardized test score is constructed by taking the average of the standardized test score from the three tests. Individual tests are standardized by using the sample mean and standard deviation for the relevant test. Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Table 4: Average performance (engagement in training) by treatment group

| Dependent Variable | Engagement in training | | | | | Performance Index |
|------------------------------------|------------------------|-----------------------|----------------------|-------------------------|---------------------|-------------------|
| | Any contribution | Total # contributions | # good contributions | # neutral contributions | # bad contributions | |

Notes:

This table presents mean performance as measured by engagement recorded by the recruiter by treatment group. "Any contribution" is a binary indicator if the job trainee ever engaged verbally in training. The "total number of contributions" is the cumulative number of contributions made by the job trainee during the three days of training, and then separated out by quality as determined by the recruitment staff. The performance index is a summary measure of the performance indicators. It is constructed by taking the average of the normalized values of "Average test score", "Any contribution", "Total number of contributions", "Number of good contributions", "Number of neutral contributions", "Number of bad contributions". Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Table 5: Mean effort by treatment group

Notes:

This table presents the average effort by treatment group using both administrative data and survey data. "Always late" is a binary indicator equal to 1 if the job trainee ever arrived to training late. "Ever late" is a binary indicator equal to 1 if the job trainee always arrived late for training. "Minutes early/late" is a continuous variable recording the minutes early (-) or late (+) job trainees arrived at training. Time use in columns 4 and 5 comes from survey data and is the average hours reported by respondents across the 3 observations for each activity. The effort index is a summary measure of the effort indicators. It is constructed as the average of the normalized values of: "Minutes early/late", "Hours studying training materials", "Hours watching television/listening to the radio". Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Notes:

This table presents treatment group means and their interaction with different baseline covariates. Treatment status was randomly allocated and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of control variables include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For each observation, the mean value of the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is present. Standard errors are presented.

Notes:

Panel A presents employment rates (with recruiter) by treatment group.

Panel B presents the impact on employment of the 0-, 1-, 5-, 50-, 75- job probabilities treatment compared to the 100 percent treatment group where employment risk is 0.

Columns 1 through 3 present results for the full sample, while Columns 4 through 6 exclude those that did not attend all training days.

Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented. *** indicates significance at the 1% level, ** indicates significance at the 5% level, * indicates significance at the 10% level

Table 8: Alternative Explanations?

| Average | Attendance | Food Expenditures (in MKW) | Eat out Expenditures (in MKW) | Perceived chance of employment with recruiter | Happiness |

| Observations | 268 | 256 | 256 | 256 | 256 |
| R-squared | 0.97 | 0.36 | 0.6 | 0.94 | 0.8 |
| <i>p-values of F-tests:</i> | | | | | |
| 0% and 100% | 0.147 | 0.797 | 0.543 | 0.363 | 0.007 |

Notes:

This table presents the treatment group means for each outcome.

Attendance is a binary variable equal to 1 if the respondent ever attended training (i.e. attended at least one of the training days).

Food Expenditures (in MKW) is the average amount spent on food reported by the respondent across the 3 training days. "Eat out expenditures (in MKW)" is similar except measures food expenditures for food consumed away from the home.

"Perceived chance of employment with recruiter" is constructed using the following question: "What percentage chance do you think you have of getting one of the available positions for the RECRUITER'S PROJECT?" with the following options: No chance of getting a job; Less than 25 percent; Between 25 and 50 percent; 50 percent; Between 50 and 75 percent; Between 75 and 99 percent; and Certain about employment with recruiter. To create a measure of the likelihood of employment I assign the mid-point to categories that are brackets and creating a continuous variable.

Happiness is measured using the question: "How happy are you right now (where 0 = extremely unhappy; and 10 = extremely happy). This was only asked on 2 of the follow-up survey questionnaires, therefore this is an average of 2 rather than 3 observations.

Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

| R-squared | 0.11 | 0.25 | 0.26 | 0.31 | 0.32 |
| Average of dep variable | | | 0.158 | | |

Notes:

The dependent variable is a binary indicator equal to 1 if the recruiter offered the job-seeker a job and 0 otherwise. The test score and ability score are standardized using the full sample mean and standard deviation. For covariates with missing data the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors. *** indicates significance at the 1% level, ** indicates significance at the 5% level, * indicates significance at the 10% level

Appendix Table 2: Probit regressions for binary performance and effort indicators

| Dependent Variable | Any contribution | Ever late | Always late |

| 100% Job Guarantee | -0.051 [0.142] | -0.022 [0.104] | 0.026 [0.145] |
| Observations | 262 | 256 | 262 |
| Additional controls? | Yes | Yes | Yes |
| Stratification cell fixed effects? | Yes | Yes | Yes |

Notes:

"Any contribution" is a binary indicator if the job trainee ever engaged verbally in training. "Ever late" is a binary indicator equal to 1 if the job trainee always arrived late for training. "Always late" is a binary indicator equal to 1 if the job trainee ever arrived to training late. Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Notes:

This table presents the average training classroom behavior by treatment group using administrative data. "Any disruption" is a binary indicator equal to 1 if the job trainee at any point during training disrupted the training to exit the room, to take a phone call or was disruptive by talking to his peers or making noise. "Number of disruptions" is the cumulative number of disruptions made by a job trainee. Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Appendix Table 4: Arrival time distribution tests of equality

Minutes early/late: p-value of kolmogorov smirnov distribution test of equality

| | 0% Job Guarantee | 1% Job Guarantee | 5% Job Guarantee | 50% Job Guarantee | 75% Job Guarantee | 100% Job Guarantee |

| 0% and 100% | 0.069 | 0.235 | 0.181 | 0.077 | 0.203 | 0.114 |

Notes:

This table presents mean performance using multiple measures per individual. Individual test scores are standardized by using the sample mean and standard deviation for the relevant test. "Any contribution" is a binary indicator if the job trainee engaged verbally on any particular training day. The "total number of contributions" is the cumulative number of contributions made by the job trainee per day, and then separated out by quality as determined by the recruitment staff. The performance index is a summary measure of the performance indicators. It is constructed by taking the average of the normalized values of "Test score", "Any contribution", "Total number of contributions", "Number of good contributions", "Number of neutral contributions", "Number of bad contributions". Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Appendix Table 6: Effort Indicators Robustness Check: Panel

| | Late | Mins early or late | Studied (Hours) | Radio/TV (Hours) |
|---------------------------|------------------|-------------------------------|----------------------------|-----------------------------|

| 0% and 100% | 0.494 | 0.325 | 0.001 | 0.000 |

Notes:

This table presents the average daily effort by treatment group using both administrative data and survey data. "Late" is a binary indicator equal to 1 if the job trainee arrived late for training on that day. "Minutes early/late" is a continuous variable recording the minutes early (-) or late (+) job trainees arrived at training. Time use in columns 4 and 5 comes from survey data and is the number of hours conducting each activity daily. The effort index is a summary measure of the effort indicators. It is constructed as the average of the normalized values of: "Minutes early/late", "Hours studying training materials", "Hours watching television/listening to the radio". Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Appendix Table 7: Performance Indicators (No covariates)

| Observations | 259 | 259 | 259 | 254 | 254 |
| R-squared | 0.238 | 0.043 | 0.647 | 0.699 | 0.676 |
| <i>p-value of F-test:</i> | | | | | |
| 0% and 100% | 0.347 | 0.306 | 0.316 | 0.008 | 0.002 |

Notes:

This table presents the average effort by treatment group using both administrative data and survey data. "Ever late" is a binary indicator equal to 1 if the job trainee ever arrived late for training. "Always late" is a binary indicator if the job trainee arrived late for training every day. "Minutes early/late" is a continuous variable recording the average minutes early (-) or late (+) job trainees arrived across the training period. Time use in columns 4 and 5 comes from survey data and is the average number of hours conducting each activity. Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Appendix Table 9: Omitted variable bias ratio

| | Ratio (1) |
|--|----------------------|
| <i>Performance indicators:</i> | |
| Tests | 67.994 |
| <i>Engagement:</i> | |
| * # of contributions | -1.504 |
| * # good contributions | -1.672 |
| * # neutral contributions | -1.796 |
| * # bad contributions | -0.703 |
| <i>Effort indicators:</i> | |
| <i>Punctuality:</i> | |
| * Ever late | -3.980 |
| * Always late | -6.379 |
| * Minutes early/late | -4.279 |
| <i>Time use:</i> | |
| * Hours studied training materials | 7.003 |
| * Hours watching tv/listening to radio | 9.668 |

Notes:

Following Altonji et al. (2005) and Bellows and Miguel (2008), I construct a ratio that assesses the extent of omitted variable bias that would be required to explain away the results. This table presents the ratios for each of the performance and effort indicators for the estimated difference between those assigned no outside option and a guaranteed outside option. The ratio measures the extent to which selection on unobservables would need to exceed selection on observables to explain away the coefficient. Therefore, a larger ratio implies that the relative omitted variable bias from unobservables relative to observables is greater, and therefore estimated effects are less likely to be explained away.

Appendix Table 10: Average performance by treatment group: Weighted results and Bounds

| | Average test score | | | Number of contributions | | | Good quality contributions | | | Neutral quality contributions | | |

Notes:

This table presents mean performance using an average across training for each job trainee. I use the average of the standardized test scores which are standardized by using the sample mean and standard deviation for the relevant test. "Any contribution" is a binary indicator if the job trainee engaged verbally ever during training. The "total number of contributions" is the cumulative number of contributions made by the job trainee during the whole training, and then separated out by quality as determined by the recruitment staff. Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

| <i>Time use:</i> | | | | | |
| * Hours studied training materials | -0.502 | 0.001 | -0.363 | 0.021 | 9.43 |
| * Hours watching tv/listening to radio | 0.656 | 0.032 | 1.043 | 0.001 | 9.43 |

Notes:

This table presents the Lee bounds for the comparison of those assigned no outside option (T0) and those assigned a guaranteed outside option (T100). I use the average of the standardized test scores which are standardized by using the sample mean and standard deviation for the relevant test. "Any contribution" is a binary indicator if the job trainee engaged verbally ever during training. The "total number of contributions" is the cumulative number of contributions made by the job trainee during the whole training, and then separated out by quality as determined by the recruitment staff. "Late" is a binary indicator equal to 1 if the job trainee arrived late for training on that day. "Minutes early/late" is a continuous variable recording the minutes early (-) or late (+) job trainees arrived at training. Time use in columns 4 and 5 comes from survey data and is the number of hours conducting each activity daily. The effort index is a summary measure of the effort indicators. It is constructed as the average of the normalized values of: "Minutes early/late", "Hours studying training materials", "Hours watching television/listening to the radio".

Appendix Table 12: Average effort indicators: Weighted results and bounds

| | Punctuality | | | Hours studied training materials | | | Min-Max Bounds | | |
|----------------------------|----------------|---------|---------|----------------------------------|---------|---------|----------------|---------|---------|
| | Min-Max Bounds | | | Min-Max Bounds | | | Min-Max Bounds | | |

Notes:

This table presents the average daily effort by treatment group using both administrative data and survey data. "Late" is a binary indicator equal to 1 if the job trainee arrived late for training on that day. "Minutes early/late" is a continuous variable recording the minutes early (-) or late (+) job trainees arrived at training. Time use in columns 4 and 5 comes from survey data and is the number of hours conducting each activity daily. The effort index is a summary measure of the effort indicators. It is constructed as the average of the normalized values of: "Minutes early/late", "Hours studying training materials", "Hours watching television/listening to the radio". Treatment status was randomly allocated and stratified by quintile ability and prior work experience with the recruiter. The stratification cell fixed effects include a set of dummies for each stratification cell. The set of additional covariates include: a dummy variable for whether the individual has worked before, marital status, age, and the individuals' standardized ability score. For covariates with missing observations the variable is assigned the mean value of the variable and an indicator variable is included for whether or not that particular variable is missing. Robust standard errors are presented.

Appendix Table 13: Average effort indicators: Weighted results and bounds

| | Perceptions | | | Food expenditures - groceries | | | Food expenditures - eat out | | | Happiness | | |
|----------------------------|-----------------|---------|---------|-------------------------------|-----------|----------|-----------------------------|----------|----------|-----------------|---------|---------|

Notes:

This table presents the treatment group means for each outcome.

Attendance is a binary variable equal to 1 if the respondent ever attended training (i.e. attended at least one of the training days).

Food Expenditures (in MKW) is the average amount spent on food reported by the respondent across the 3 training days. "Eat out expenditures (in MKW)" is similar except measures food expenditures for food consumed away from the home.

"Perceived chance of employment with recruiter" is constructed using the following question: "What percentage chance do you think you have of getting one of the available positions for the RECRUITER'S PROJECT?" with the following options: No chance of getting a job; Less than 25 percent; Between 25 and 50 percent; 50 percent; Between 50 and 75 percent; Between 75 and 99 percent; and Certain about employment with recruiter. To create a measure of the likelihood of employment I assign the mid-point to categories that are brackets and creating a continuous variable.

Happiness is measured using the question: "How happy are you right now (where 0 = extremely unhappy; and 10 = extremely happy). This was only asked on 2 of the follow-up survey questionnaires, therefore this is an average of 2 rather than 3 observations.

Appendix Table 14: Perceptions Distribution Tests

| Perception Distribution (average): p-value of kolmogorov smirnov distrinbution test of equality | | | | | | |
|--|------------------|------------------|------------------|-------------------|-------------------|--------------------|
| | 0% Job Guarantee | 1% Job Guarantee | 5% Job Guarantee | 50% Job Guarantee | 75% Job Guarantee | 100% Job Guarantee |
| 0% Job Guarantee | | 0.987 | 0.984 | 0.068 | 0.156 | 0.933 |
| 1% Job Guarantee | | | 0.975 | 0.157 | 0.472 | 0.705 |
| 5% Job Guarantee | | | | 0.083 | 0.615 | 0.903 |
| 50% Job Guarantee | | | | | 0.004 | 0.012 |
| 75% Job Guarantee | | | | | | 0.952 |
| 100% Job Guarantee | | | | | | |

Notes:

This table presents the associated p-values from Kolmogorov distribution tests of equality between the distribution of arrival times between treatment groups. Perceived chance of employment with recruiter is constructed using the following question: “What percentage chance do you think you have of getting one of the available positions for the RECRUITER’S PROJECT?” with the following options: No chance of getting a job; Less than 25 percent; Between 25 and 50 percent; 50 percent; Between 50 and 75 percent; Between 75 and 99 percent; and Certain about employment with recruiter. To create a measure of the likelihood of employment I assign the mid-point to categories that are brackets and creating a continuous variable.
